Abstract

Maize ear fasciation originates from excessive or abnormal proliferation of the ear meristem and usually manifests as multiple-tipped ear, ear flatness and/or disordered kernel arrangement. Ear prolificacy expresses as multiple ears per node. Both traits can affect grain yield. In this study, the genetic control of the two traits was analyzed using two recombinant inbred lines (RIL) populations (B73 × Lo1016 and Lo964 × Lo1016) with Lo1016 and Lo964 as donors of ear fasciation and prolificacy, respectively. Four ear fasciation-related traits (ear fasciation, kernel distribution and ear ovality indexes and ratio of ear diameters), number of kernel rows, ear prolificacy and number of tillers were phenotyped in multi-year field experiments. Ear fasciation traits and number of kernel rows showed relatively high heritability ($h^2 > 0.5$) except ratio of ear diameters, and showed correlation. Prolificacy and tillering h^2 ranged 0.41 - 0.78 and did not correlate. QTL mapping identified four QTL for ear fasciation, on chr. 1 (two QTLs), 5 and 7, the latter two overlapping with QTLs for number of kernel rows. However, the strongest effect QTL for number of kernel rows mapped on chr. 2 independently from ear fasciation. Four and five non-overlapping QTLs were mapped for ear prolificacy and tillering, respectively. Two ear fasciation QTLs from this study, *qFas1.2* and *qFas7*, overlapped with formerly known fasciation QTLs and spanned candidate genes expressed in ear meristems namely *compact plant2* and *ramosa1*. Our study identified novel ear fasciation, ear prolificacy and tillering loci which are unexpectedly still segregating in elite maize materials, and provides foundation for genomics-assisted breeding for yield components.

1. Introduction

Fasciation is a deviational proliferation of cells and tissues eventually manifesting as widen and flattened organs, most commonly arising from indeterminate tissues of actively growing organs such as stems or inflorescences, reported in more than 107 plant families, including trees, shrubs and grasses (White, 1948; Iliev and Kitin, 2011) . Fasciation was interpreted as (i) an excrescence or fusion of organs due to deviations from normal meristematic processes or crowding of buds, or (ii) a transformation of a single growing point into a line, this sometime called 'true fasciation' (Clark *et al.*, 1993; Iliev and Kitin, 2011) .

Fasciation can originate as a consequence of natural factors artificial treatments, or by mutations (Iliev and Kitin, 2011; Ortez *et al.*, 2022) . Fasciated mutants can be of interest in plant breeding programs for their ornamental characteristics or because their abnormal development may favorably affect yield components such as fruit and/or seed size and number. This is the case for tomato cultivars where fasciation contributed to increase the number of fruit locule and fruit size (Tanksley, 2004; Iliev and Kitin, 2011) , for a mutation in mustard (*Brassica rapa*) at the *Multilocular* locus, which increases seed production (Fan *et al.*, 2014), and for maize, where it has been suggested as a potential target for increasing ear size and/or number of kernels per ear, which are important yield components (Kim *et al.*, 2022; Somssich *et al.*, 2016). The interest in the connection between fasciation and grain yield components in maize increased in the last decades as the knowledge about the molecular control of the inflorescence meristem development accumulated. Accumulating evidences indicated that while strong fasciated ear mutants do not improve productivity as they usually lead to a shorter stunted ear, weaker alleles leading to a less disturbed inflorescence meristem show more potential to improve yield (Bommert, Nagasawa, *et al.*, 2013; Je *et al.*, 2016; Kim *et al.*, 2022; Ortez *et al.*, 2022).

Size and shape of the shoot vegetative meristem or of the early generative inflorescence meristem were early recognized as the developmental foci where genetic defects could determine the production of a fasciated inflorescence (Galli and Gallavotti, 2016; Kyozuka *et al.*, 2014). One of the key regulation pathways is the CLAVATA3 (*CLV3*)-WUSCHEL (*WUS*) feedback signaling which controls stem cell proliferation and tissue and organ differentiation

(Somssich *et al.*, 2016). This mechanism is achieved based on a negative-feedback loop mainly consisting of the stem cell-promoting transcription factor, WUSCHEL, and the differentiation-promoting peptide *CLV3* that is expressed only in stem cells of the shoot apical meristem (SAM) and belongs to CLAVATA3/EMBRYOSURROUNDING REGION (ESR) CLE peptide family (Trotochaud *et al.*, 1999; Opsahl-Ferstad *et al.*, 1997). With this loop, WUS activities are firstly repressed by an extracellular protein encoded by *CLV3*, causing decline of stem cell multiplication, and correspondingly, decrease in *CLV3* production (Brand *et al.*, 2000; Schoof *et al.*, 2000). Therefore, such parallel feedback mechanism keeps the size of the organizing center, in terms of number of cells, under control (Müller *et al.*, 2006).

CLV-WUS meristem size regulatory pathway acts across plant species, including crops such as maize, rice and tomato. For example, an ortholog of *CLV3* in rice, *FLORAL ORGAN NUMBER 2* (*FON2*) (also identified and named independently as *FON4*) was found to express specifically in a few cells in the shoot apical region and is responsible for regulating floral organ number (Chu *et al.*, 2006; Suzaki *et al.*, 2004), while another *CLV3* ortholog in maize, *ZmFCP1*, is mainly expressed in leaf primordia (Rodriguez-Leal *et al.*, 2019), unlike its counterpart, *FCP1* in rice (Suzaki *et al.*, 2008) which is expressed in shoot. In *fea3* mutants in maize, SAM size showed significant decline when *ZmFCP1* peptides and *fea3* embryos showed resistance only to *ZmFCP1*, indicating *FEA3* functions as a receptor of *ZmFCP*1 (Somssich *et al.*, 2016). In contrast, *FEA2*, the *CLV2* ortholog in maize, involved more widely in regulating activities of correlated CLE peptides, including *ZmCLE7* and *ZmFCP1*, *ESR2c* (Je *et al.*, 2018), and *fea2*-null mutants have larger KRN compared with wild-type plants, as there are 30 or more irregular kernel rows in mutants (Bommert, Nagasawa, *et al.*, 2013). Similarly, a downstream effector, *COMPACT PLANT2* (*ct2*) is also able to achieve signaling transition from these distinct CLE peptides, suggesting the whole mechanism appears like the CLV-WUS pathway in *Arabidopsis* (Bommert, Nagasawa, *et al.*, 2013).

Besides these, other genes have been identified which function is not completely clear, however their mutants showed evident ear fasciation. For example, in the mutants of *UNBRANCHED3* (*UB3*), the size of the inflorescence meristem is mediated positively and kernel row number is increased, suggesting *UB3* regulates vegetative and reproductive

branching in maize (Du *et al.*, 2017). Additionally, the QTL *KERNEL ROW NUMBER4* (*KRN4*), mapped in an intergenic region on chr 4 (Liu, Du, Shen, *et al.*, 2015), nearby *UB3*, was recognized as a *cis*-regulatory element of *UB3* (Du *et al.*, 2020) *UB2*, a paralog of *UB3*, also encoding SBP-box transcription factors, plays a redundant role with *UB3* in controlling the initiation of reproductive axillary meristems and interacts physically with *KRN4* (Du *et al.*, 2020).

As already anticipated, most of these traditional mutants showed negative pleiotropy on grain yield and it has been difficult to utilize them directly in breeding. For example, fasciated ear mutants such as ramose mutants, *ra1*, *ra2* and *ra3*, usually develop shorter ears with disordered seed rows, resulting in decreased kernel number. More promising seems to be the use of some weaker alleles for the same genes, possibly in heterozygosity in F_1 hybrid combinations (Bommert, Je, *et al.*, 2013; Bommert, Nagasawa, *et al.*, 2013; Gallavotti *et al.*, 2010).

In maize, prolificacy is a general term indicating the presence of multiple ears in a plant and can be classified as three types: multi-node prolificacy (multiple ears growing at different nodes), multi-tiller prolificacy (multiple stems grow from nodes), and single-node prolificacy (multiple ears growing at the same nodes, also known as 'multi-ears' or 'bouquet ears' or 'shank ears'; (Ortez *et al.*, 2022). In this study we will specifically focus on single-node prolificacy. In single-node prolificacy, the presence of multiple ears is the result of multiple axillary meristems located on the same ear shank giving rise to additional ear inflorescences alongside the central one. Their developmental timing is assumed to be early, starting from stages V4-V6, however it can extend up to pollination (Abendroth, L.J., Elmore, R.W., Boyer, M.J., and Marlay, S.K., 2011). The presence a single major ear per plant versus multiple ears is one the major contrasting difference between currently cultivated maize and its progenitor teosinte (Stitzer and Ross-Ibarra, 2018). Because of this, domesticated maize was referred as "not prolific", while its progenitor teosinte as "prolific" (Yang *et al.*, 2019; Doebley *et al.*, 1995; Prakash *et al.*, 2019). While most of the modern maize hybrid cultivars cultivated in the high-dense stands in temperate environment develop only one ear, the potential presence of multiple ears per plant

has physiological and breeding implications. For instance, maize hybrid cultivars with some level of plasticity to develop tillers and multiple ears per plant may turn out advantageous in semi-arid regions with high inter-annual variation of summer rainfall, where they are cultivated at low plant population densities (i.e., less than 4 plants m-2) (Rotili *et al.*, 2022). More specifically Rotili et al. 2002 suggested that a multiple-ear genotype could provide higher yield when the environmental conditions would have prevented the development of tillers, in a cropping system characterized by low plant density. Another situation where ear prolificacy is considered a positive feature is in cultivars utilized for baby corn production used for human consumption. Baby corn is a type of specialty food where unfertilized maize ears are consumed in salads, soups, fried snacks etc. Major baby corn markets exist in United Kingdom, United States of America, Malaysia, Taiwan, Japan and Australia, which mainly import baby corn from international markets especially Thailand (Prakash *et al.*, 2019).

The genetic control of multiple ears per plant is complex, as it involves at least three different mechanisms as introduced above. However, only a few studies have so far addressed the genetic control of this trait. A major QTL for single-node prolificacy, *prol1.1,* was mapped on chr. 1 in a maize-teosinte BC_2S_3 population, at a chromosomal location that has previously been shown to influence domestication traits. The authors identified *prol1.1* ‘‘causative region’’ as a transposon insertion upstream of the *grassy tillers1* (*gt1*) gene, which encodes a homeodomain leucine zipper transcription factor (Wills *et al.*, 2013). Prakash et al (2021) took advantage of a multi-node prolific maize inbred characterized by five to nine ears per plant to cross two non-prolific inbred. Results showed that a sizeable portion of prolificacy phenotypic variation (c. 30%) was controlled by a major locus in bin 8.05 between umc2199 and bnlg1031. Multi-node prolificacy was also addressed in a large study involving two experimental RIL populations and one germplasm collection leading to the identification of several QTL on all chromosomes (Wang *et al.*, 2021).

It should be noted that ear and tillers both originate from axillary buds developing into shorter or longer shoots, therefore they are expected to share an important portion of genes and regulatory mechanisms. This was indeed confirmed by the identification and cloning of genes such as *BARREN STALK1* (*BA1*), encoding a bHLH transcription factor orthologous to rice

LAX PANICLE1 (*LAX1*) (Gallavotti et al. 2004). ba1 mutants fail to initiate all vegetative and reproductive axillary meristems. *BA1* levels are under the control of *BARREN STALK FASTIGIATE1* (*BAF1*), a transcriptional regulator with an AT-hook DNA binding motif (Gallavotti et al. 2011). Mutant *baf1* plants fail to initiate axillary buds that are fated to become lateral ear shoots; as a result, *baf1* mutants are earless (Gallavotti et al. 2011).

Conventional breeding methods applied to maize and other crops basically depend on phenotypic selection in order to identify filial individuals to be deployed as new cultivars. In maize, these progenies should also be characterized by heterosis (or even heterobeltiosis, namely the superiority of the F1 hybrid to the best parent). The process is extremely complex, and time and resource expensive. In order to overcome limitations in traditional breeding, marker assisted selection (MAS) was introduced as an efficient supplementary method, in which differences of genetic sectors involved in agronomic phenotypes under studying are able to be recognized by molecular markers. By developing an array of molecular markers and genetic maps, and building correlations between genotypes and phenotypes, it is more likely to map those quantitative trait loci (QTL) and functional genes, thus accelerating the breeding process. With availability of cheaper sequencing technologies, utilization of molecular markers appears a gradual shift from simple sequence repeats (SSRs) to single nucleotide polymorphisms (SNPs) in mapping studies (Choudhary *et al.*, 2019). Additionally, a more cutting-edge technology in maize breeding is the application of CRISPR-CAS9 system for gene editing. This system is similar to scissors, cutting the DNA, or genes at a particular spot, usually called as the binding site, resulting in elimination, adding, or overexpression of the target genes. (Agarwal *et al.*, 2018)

Besides adequate molecular markers, mapping populations with sophisticated design are also required in order to verify genetic sectors with phenotypic variation, thus linking polymorphism with traits. Types of mapping population which were applied ever and are utilized presently include second filial generation (F_2), backcross (BC), recombinant inbred lines (RILs), double haploids (DHs), and near isogenic lines (NILs), in which F_2 and BC carry the most convenient experimental populations designed for self-pollination crops, deriving from selfing F_1 hybrids which are developed by crossing of two parent lines and from crossing

F_1 lines with one of the parents respectively, on the base of which two three other populations are allowed for creating. For example, recombinant inbred lines originate from inbreeding from individual F_2 plants after 7-8 generations, which ensures that a series of offspring lines are homozygous and each individual carries a unique recombination segment from the two initial parents, and near isogenic lines are developed by generational backcross selection by at least 6 times and then selfing BC_7 by two generations, aiming to screen lines carrying homozygous sectors for the target genes (Glover *et al.*, 2004). Doubled haploid (DH) populations could be produced through both *in vivo* and *in vitro* systems, such as by parthenogenesis, pseudogamy or chromosome elimination after extensive crossing in order to nurture haploid embryos, in spite of restricted application only in species enabling to culture tissues, including crop (barley, maize, rice etc.) and tree species (oak etc.) (Maluszynski *et al.*, 2014).

According to Xu (Xu, 2012), several classification standards could be applied in order to describe their properties genetically based on genetic constitution, maintenance and genetic background of progeny populations. According to the first classification, mapping populations constructed could be divided into four types: homogeneous populations with homozygous individuals, including individuals originating from an inbred developed by open pollination; homogeneous populations with heterozygous individuals, such as F1 plants crossed by two homogeneous individuals in an open-pollinated population; Heterogenous populations with homozygous individuals, such as RIL populations; Heterogenous populations with heterozygous individuals, such as F2 populations. According to the second classification, they could be separated into two types based on whether the genetic constitution of a population could be maintained after selfing by one or more generations: Temporary populations, including F2, BC populations since segments of their chromosome would create recombination as selfing or inbreeding, resulting in utilization only once; Permanent populations, such as RIL, NIL populations, because these types of populations consist of a set of pure-breeding lines, which means that they have almost identical genotypes across the whole genome except minor alleles distributed randomly. Besides, it appears extremely simple to divide based on genetic background by which these populations could be separated from those which have nearly isogenic background and those which have heterogenous backgrounds.

Additionally, in the past decade years, more complex mapping populations have been proposed and applied in both association and linkage mapping practically. Multi-founder populations recognized as a second-generation mapping approach, different from bi-parental populations which are symbolled with small scales and underpowered, are initially designed for mapping multiple QTL for a series of phenotypes despite more expending on labor and time required when creating such populations, in which Nested-association-mapping (NAM) populations, Multiparent advanced generation intercross (MAGIC) populations are the two widely applied.

Nested-association-mapping (NAM) population, firstly proposed by Yu (Yu *et al.*, 2008) in 2008 in order to proceed outcrossing in maize and firstly published by McMullen (McMullen *et al.*, 2009) in 2009 consisting of 25 maize inbred lines crossing with a common recurrent parent B73 and developing 5,000 RILs finally, enables combination of advantages of linkage mapping and association mapping parallelly: substantial scales of populations provide enough power to map loci in the linkage analysis with less need for high density markers, while the utilization of more rapidly decaying LD across the multiple founders improves precision in the association mapping (Yu *et al.*, 2008). However, NAM populations face a major limitation: no novel haplotype would be generated when only one common parent is used. This defect could be remedied in Multiparent advanced generation intercross (MAGIC) populations, another mapping approach when multi-parents are used. MAGIC is developed by intercrossing multiple founders (typically eight) with multiple rounds before construction of offspring lines for genetic mapping, and 28 possible F1 (2-way) crosses and 210 possible four-way crosses among unrelated F1s and another 315 possible ways of creating the eight-way crossed exist (Mackay *et al.*, 2014). This type of populations has been utilized involve in many important crops, including rice (Bandillo *et al.*, 2013; Meng *et al.*, 2016), wheat (Huang *et al.*, 2012; Mackay *et al.*, 2014), maize (McMullen *et al.*, 2009), and tomato (Pascual *et al.*, 2015). MAGIC populations bear representative beneficial factors compared with bi-parental and/or identical association-mapping populations: Firstly, more abundant genetic variations exist across the whole genome when involving in multiple parent lines; Secondly, frequencies of alleles are more balanced due to the equal contribution of founder to the whole population; Thirdly,

recombination events are proximately densely and evenly distributed, thus providing substantial resolution for constructing genetic maps and isolating target genes.

In this study, we investigated the genetic control of ear fasciation and ear prolificacy and the connection of these traits with kernel row number and tillering, respectively. We addressed this by exploiting two RIL populations, B73 × Lo1016 and Lo964 × Lo 1016, which are all elite maize dent lines. Lo1016 is an inbred line characterized by mild ear fasciation, while Lo964 is characterized by multiple-ear at single node.

2. MATERIALS AND METHODS

Plant materials and marker genotyping

Two recombinant inbred line (RIL) populations were developed at DISTAL, University of Bologna, as follow. The Italian-origin inbred line Lo1016 was crossed with B73 and with Lo964, a second inbred line originated from Italy to create two F_1s. Both Lo964 and Lo1016 were bred at the Bergamo breeding station (Italy), shown to be relatively related based on molecular marker analysis, and classified to the BSSS = Iowa Stiff Stalk Synthetic heterotic group (Alessia Losa, Hans Hartings, Alberto Verderio, Mario Motto, 2011). B73 is the maize inbred line of reference (Schnable *et al.*, 2009). We proceeded by single seed descent method until F7. Since the F7 stage, seeds from each line were obtained and multiplied following standard procedures. The RIL B73 × Lo1016 (B×L) and Lo964 × Lo1016 (L×L) eventually included 97 and 68 recombinant inbred lines, respectively. We will refer to Joint Population (JP) as the assembly of whole set of 165 (97 + 68) RIL lines.

Field experiment and phenotypic data collection

Field trials for the phenotypic analysis of ear fasciation and ear prolificacy, including the two RIL populations and parental lines were carried out in Cadriano, near Bologna, Italy (44°33'02.5"N, 11°24'43.9"E) in 2017 and in Monselice, near Padua, Italy (45°12'42.4"N,

11°45'14.8"E) in 2018 and 2019. Field experiments were organized as randomized complete block design with two replicates (one rep = one plot with 10 plants per RIL line). Plots for each of the three parental lines were included in the experiment. Plot length was 2.5 m, distance between rows was 0.8 m and between plants was 0.17 m. Plots were overplanted by hand and thinned at the V7 growth stage to one plant per hill equivalent to ten plants per plot, and with an overall investment of 10 plants per square meter. The field management followed standard agronomic practices of the area.

Phenotyping for ear fasciation was addressed by collecting four traits, namely 'ear ovality' (OVA, defined after visual inspection of elliptic/flatness degree of cob cross-section, from 0 to 10, corresponding from perfect circle to extremely elliptic/flat cob cross sections, respectively; higher values indicated strong fasciation); 'kernel row disorder' (DIS, defined as a visual score for from 0 to 10, corresponding from perfectly linearly arranged kernels on ears to highly disordered arrangement, respectively; higher values indicated strong fasciation); 'ear diameter ratio' (DIA, defined as ratio of minimum diameter divided by maximum diameter, where the two diameters were measured mutually perpendicularly by a vernier caliper at the middle of maize ear; lower values corresponded to strong fasciation); 'ear fasciation' (FAS, a visual score for ear fasciation scaled from 0 to 3, where 3 indicated a strongly fasciated ear). Visual scores per ear were given by three persons independently, and mean values were utilized as entries for subsequent analysis. Number of kernel rows (KRN) was collected by counting the number of kernel rows at mid ear position, on the same ears subjected to phenotyping for fasciation. Plant architecture traits collected were number of tillers per plants (TIL) and proportion of plants per plot showing prolificacy (i.e. >1 ear at the top ear node, PROL).

Raw phenotypic data for all traits were modified by using the model Best Linear Unbiased Estimator (BLUES) in the R package "tidyverse"(Wickham *et al.*, 2019). BLUES values were utilized for biometric summary, and correlation and QTL analysis. Correlation analysis was carried out by Spearman method (Wickham *et al.*, 2019) (although we will use the common letter '*r*' instead of the more appropriated '*rho'* for clarity in text) which is less sensitive to deviation from normal distributions. All trait phenotypic distributions were normal or close to normality with the exception of TIL and PROL. For these traits, original distributions

resembled Poisson distribution (Fig. 2 and supp. Fig 1 and 2). While we used original data for visualization, we operated a square root transformation as suggested in (Sokal and Rohlf, 2012) for the datasets to be used for QTL mapping.

SNP genotyping, construction of linkage map and QTL mapping

B×L and L×L were genotyped using a high density 15K SNP array (Rousselle *et al.*, 2015) using a commercial service. Genomic DNA was prepared following standard protocols by a DNA extraction kit (NucleoSpin Plant II, Macherey Nagel, Duren, Germany) based on the manufacturer's protocol. Marker alleles from Lo1016 were coded as 0, alleles from Lo964 and B73 were coded as 2, and missing values were coded as -1. Linkage map construction was obtained using Icimapping (Meng *et al.*, 2015), by first removing redundant markers using the procedure "BIN", and then building linkage maps using "MAP". Three linkage maps were constructed, one for each biparental cross RIL population, and one as joint population linkage map. For "BIN" function, markers whose missing rate is higher than 50% and distortion rate is higher than 0.01 were deleted. For "MAP" function, the algorithm nnTwoOpt and SARF (sum of adjacent recombination fractions) for rippling were applied, and the window size was specified as 9.

QTL mapping was carried by QTL Icimapping, with the function 'BIP' for RIL population and 'NAM' for the two populations analyzed as a whole (Joint Population, JP). The scanning step was set as 0.1 cM in NAM and 1 cM in BIP respectively. Probability of stepwise regression was set to 0.0001. All QTL results were produced using composite interval mapping (ICIM). The LOD threshold for declaring QTL significance was set as 3.3, 3.6 and 4.6, for B×L, L×L and JP, respectively, after permutation test ($P \leq 0.05$, 1,000 permutation). QTL additive effects were always computed considering the formula 2a = (mean homozygous B73 – mean homozygous Lo1016) or 2a = (mean homozygous Lo964 – mean homozygous Lo1016), for the two RIL populations.

Screening candidate genes and variant calling

QTL confidence intervals from this study were projected on B73 reference genome Zm-B73-REFERENCE-NAM-5.0 (Hufford *et al.*, 2021) and included gene models were considered for further investigations. Whole genome sequencing of the two lines Lo964 and Lo1016 was carried out with Illumina HiSeq PE150 at 20× of coverage. Reads were aligned to the B73v5 using BWA v.7.17 (Li and Durbin, 2009). Variants were called with BCFtools v. 1.10.2 (Li, 2011) and were filtered for a minimum reads depth of 10×, PHRED quality > 40 and a minimum DV/AD ratio of 0.8, where DP is the coverage depth at the variant position and AD is the allelic depth of the alternate allele. Variant effects were predicted with SNPEff v.3.0.7 (Cingolani *et al.*, 2012) and among variants in the gene space, only high or moderate effects were considered. Additionally, alleles sequences of candidate genes were extracted for LO964 and LO1016 from their whole .vcf files and the fasta sequences were obtained with the command bcftools consensus. The 25 NAM founder sequences were downloaded from MaizeGDB (Portwood *et al.*, 2019). The fasta sequences were aligned using MUSCLE(Edgar, 2004) from MEGAX(Kumar *et al.*, 2018). The coding sequences were obtained starting from the genomic sequence and the Zm-B73-REFERENCE-NAM-5.0_Zm00001eb.1.gff3 annotation file downloaded from MaizeGDB, using GFFRead (Pertea and Pertea, 2020). The alignment images were elaborated with Jalview (Waterhouse *et al.*, 2009). Finally, a review of published QTL and genes in maize was carried out by searching major bibliographic databases using ‘ear fasciation’, ‘prolificacy’ or ‘tillering’ terms as keywords, and information on QTL and genes physical position, bin, and type of mapping population was collected.

3. RESULTS

Trait biometrics, heritability and phenotypic correlations

Preliminary observations that Lo1016 is characterized by ear fasciation and Lo964 by ear prolificacy were confirmed in this experiment (Fig. 1 and Table 1). Lo1016 showed extreme values for ear fasciation indexes as compared to Lo964 and B73 except DIS (Tab. 1. $P < 0.01$

for all comparisons for DIA, FAS and OVA, Tukey's test). Alongside, Lo1016 also showed the highest KRN (19.75 *vs* 16.33 or 14.54, for B73 or Lo964, respectively, $P < 0.01$). Lo964 showed the highest ear prolificacy (2.75 *vs* 0.0 or 0.25, for B73 or Lo1016, respectively, $P < 0.01$). In addition, Lo1016 was the only parental line developing tillers. Values for additional plant architecture traits recorded in this study are reported in Table 1.

Broad sense heritability (h^2) for ear-fasciation traits ranged from 0.13 for DIA in L×L to 0.95 for FAS in B×L. Ear prolificacy and TIL h^2 were relatively high (ranged between 0.41 and 0.78. Table 1).

Positive transgressive segregation was observed for TIL only, with some RIL lines belonging to both populations that showed >5 tillers per plant as compared to 1.5 tillers per plant in Lo1016 (high tillering parent). Negative transgressive segregation was observed for KRN, with RIL lines from L×L showing as few as 12.7 kernel rows per ear as compared to 14.5 or 19.7 kernel rows per ear recorded for Lo964 or Lo1016. Negative transgressive segregation was also observed for DIS in both RIL populations.

All four ear-fasciation-related traits resulted highly correlated, ranging from |0.48| to |0.68| ($P < 0.001$, Fig. 2. Supp. Fig. 1, 2), with DIA negatively correlated as expected (ie. the smaller DIA score, the higher ear fasciation). Additionally, these four traits correlated with KRN, with ear fasciation index being the most correlated ($r = 0.51$) and DIA the least ($r = -0.30$. All P <0.001. Fig. 2), again with DIA as the only trait showing negative correlation. Overall, these correlation results suggested that variation for KRN and ear fasciation could partially be due to the same loci. Interestingly, ear fasciation traits showed no correlation with ear prolificacy or tillering (Fig. 2).

Linkage maps

The three linkage maps, namely B×L , L×L and JP included 1,186, 984 and 1,303 markers, and covered 1,819.52 cM, 2,504.5 cM and 1,661.0 cM, respectively (Table 2 and Supplementary Figure 2). The different linkage maps covered well the maize genome with the unavoidable exception of those regions characterized by lack of markers polymorphism due to

identity-by-decent between lines. In B×L, those regions were identified as the middle part of chr 1 between PZE-101130395 (168,493,734) and PZE-101137700 (180,295,042), accounting for 3.8% of the whole chromosome, and the upper and lower parts of chr 3, for a total of 88.7 Mb (37.6% of the chr. 3 genome). In L×L , almost the whole chr 3 resulted monomorphic and thus uninformative for QTL mapping. Additionally, deficits of polymorphic markers resulted in long intervals between markers on the upper parts of chr 4 and 7, accounting for 4.9% and 7.0% for each corresponding chromosome respectively. Overall, the 87.7% and 75.7% of the maize map was sufficiently covered by molecular markers in B×L and L×L respectively.

QTL results

Four ear-fasciation QTL were identified and ear-fasciation alleles were always contributed by Lo1016

In the following, QTL for different ear fasciation-related traits (ear diameters rate, kernel disorder, ear fasciation index, ear ovality) will be considered as the same QTL whenever their supporting intervals overlap. Four QTL for ear fasciation traits were mapped (on chr 1, *qFas1.1* and *qFas1.2*; chr 5, *qFas5;* and chr 7, *qFas7*. Table 2). *qFas1.1* and *qFas1.2* were detected for ear diameters rate and fasciation index, respectively, and mapped nearby on chr 1 (bins 1.01/1.02) within two narrow supporting intervals of <2 Mb, and both segregated within B×L only. *qFas5* was mapped on bin 5.07 for fasciation index and ear ovality and appeared to segregate mainly in L×L. *qFas7* was mapped on bin 7.02 and shown to affect ear fasciation index, ear ovality and kernel disorder in both B×L and L×L. Notably, for all *qFas* QTL, the fasciation-increasing allele was provided by Lo1016, ie. the parental line showing ear fasciation (Fig. 1), as indicated by the direction of QTL effects ($2a > 0$ in *qFas1.1*, for ear diameter rate where lower values corresponded to strong fasciation, whereas $2a < 0$ for *qFas1.2*, *qFas5* and *qFas7*. Table 2).

QTLs for Number of kernel rows (KRN) partially overlapped to ear fasciation QTLs

Five QTLs for KRN were mapped. The QTL with the strongest effect, *qKRN2*, was mapped on bin 2.02 in a < 2 Mb-supporting interval and explained 13% or 23% (JP or L×L, respectively) of phenotypic variation with a genetic effect 2a = 0.69 or 0.87 kernel rows, in JP or L×L , respectively ('+' allele from Lo964). *qKRN5* was mapped on bin 5.07, controlled 10% of phenotypic variance and showed an effect of 2a = − 0.57 kernel rows ('+' allele contributed by Lo1016). Two KRN QTLs, *qKRN7.1* and *qKRN7.2*, mapped on bin 7.02 and 7.03, respectively, and had similar genetic effect (2a = −0.62 and −0.65 kernel rows, '+' allele by Lo1016). *qKRN8* mapped on bin 8.02, with a genetic effect of 2a = −0.79 in L×L ('+' allele by Lo1016). Notably, all KRN QTLs segregated in L×L while none in B×L. *qKRN2* was the only KRN QTL with the '+' allele contributed by Lo964, while Lo1016 contributed the '+' allele in the other four KRN QTLs (Table 2). Quite interestingly, two out of five KRN QTLs overlapped with ear fasciation QTL. Specifically, *qKRN5* overlapped with *qFas5* on bin 5.05 and *qKRN7.1* with *qFas7* on bin 7.02. At both chromosome regions, the ear fasciation-increasing allele (provided by Lo1016) also increased kernel row number (Table 2), supporting the hypothesis of a functional association due to the presence of causative gene(s) affecting both ear fasciation and number of kernel rows, and in line with the observed positive correlation between the two traits (Fig. 2).

Ear prolificacy is under simple genetic control in B×L and L×L cross populations, independently from tillering

Ear prolificacy was shown to be under a relatively simple genetic control, with four QTL identified (*qProl1, qProl2, qProl4* and *qProl9.* Table 2) and the highest LOD and PVE values were provided by *qProl2* (LOD = 6.34) and *qProl9* (PVE = 16.72) respectively. More specifically, *qProl1* and *qProl4* were detected in L×L only, *qProl2* was mapped in JP, *qProl9* was mapped in B×L only. At *qProl1, qProl2* and *qProl4*, the high ear prolificacy parent Lo964

contributed the '+' QTL allele. Both *qProl1* and *qProl2* were mapped in narrow physical supporting intervals (0.8 Mb and 3.3 Mb, respectively).

Tillering variation was also shown to be under a relatively simple genetic control, with four QTL mapped. The two strongest QTLs in terms of genetic effect, *qTil1* and *qTil2*, mapped on bin 1.05 and 2.01, controlled 12-13% of phenotypic variance (in JP) with a genetic effect of 2a = 0.6 tillers per plant (in JP). The '+' allele was contributed by Lo1016 for *qTil1, qTil4 and qTil9,* in both B×L and L×L, however, B73 contributed a (+) tillering allele at *qTil2*. No overlap was found between prolificacy and tillering QTL.

Ear fasciation and KRN QTLs on chr 1, chr 5 and chr 7 overlap with QTLs from former studies

We additionally investigated overlaps of ear fasciation and kernel row number QTL between our and other studies by producing QTL consensus maps obtained by projecting QTL on the same reference map (Figure 4, Supp Table 4). On the same consensus map major candidate genes were also projected. This analysis showed that *big grain1 homolog1* (*bgh1*) (Simmons *et al.*, 2020) and *compact plant2* (*ct2*) (Bommert, Je, *et al.*, 2013) two cloned genes affecting proliferation of ear primordium were positioned in the interval of *qFas1.2*. Interestingly, QTLs for cob flatness and KRN (*qCF1* and *qKRN1a*) were mapped at this region too by Mei et al (Mei *et al.*, 2021) (Figure 4). On chr 5, *qFas5* and *qKRN5* from our study overlapped with a KRN QTL (*qKRN5-4*) identified by Liu et al (Liu, Du, Huo, *et al.*, 2015). The higher level of overlapping with QTLs and genes from former studies was observed for our QTLs *qFas7 – qKRN7.1* on bin chr 7.02. At this position, overlaps were identified with fasciation QTLs from different independent studies such as *qCF7* and *qEF7* by Mei et al (2020) and *fa_c1* by Mendes et al (2015). Additionally, this ear fasciation locus overlapped with several KRN QTLs from different studies: Ear row number QTL from seven NAM crosses (Brown *et al.*, 2011); *qKRN7* (Mei *et al.*, 2021) , *EB7.1* (Chen *et al.*, 2019a); *qKRN7.1*, this study. Genes known to be involved in early ear development and/or expressed at the same stage

and included within the *qFas7/qKRN7.1* QTL supporting intervals are *ramosa1* (*ra1*) (Dempewolf, 2010) (further details below).

As far as ear prolificacy is concerned, a QTL consensus map has seen an obvious overlapped region between *qProl4* (4:148,677,638..181,859,161) and *prol4.1* (4:161,087,836.. 169,167,836) from Wills (Wills *et al.*, 2013) (Figure 4, Supp Table 5), both of which carry relatively high LOD values (6.22 and 6.48, respectively), indicating that it is worthy focusing efforts on fine-mapping of this region. Additionally, it should be mentioned that *qProl1* mapped in the proximity (2 Mb from the QTL mapped in Liu et al. 2019) of three ear prolificacy QTLs formerly identified in other studies (Wills *et al.*, 2013; Chen *et al.*, 2019b; Liu *et al.*, 2019) at chr 1, bin 1.01 (Figure 4, Supp Table 5), thus this chromosome region could be considered a potential single locus responsible for controlling ear prolificacy variation across maize germplasm.

Meristem genes *Compact plant2* (*ct2*), *Ramosa1* (*ra1*) co-map with QTL for ear fasciation *qFas1.2* and *qFas7*, and *Barren inflorescence 1 (bif1)* comaps with *qKRN8*.

In order to search for candidate genes of ear fasciation QTLs identified in this study, we extracted all gene models included in the QTLs supporting intervals present in B73 v4 (www.maizegdb.org) along with gene expression information in meristem and ear primordium. Alongside, a list of 42 genes involved in development and/or proliferation of ear meristem was collected by meta-analysis (Supp Table 2), thus a series of cloned genes positioned in QTL of this study being listed in Supp Tab 3, such as *compact plant2* (*ct2*) and *big grain1 homolog1* (*bgh1*) within *qFas1.2*, and *ramosa1* (*ra1*) with *qFas7*.

For instance, at *qFas1.2* (chr 1, 16.0 - 18.0 Mb), *compact plant2* (*ct2*) and *big grain1 homolog1* (*bgh1*) at chr 1, 16.7 Mb were identified as candidate genes, and at *qFas7*/*qKRN7.1* (chr 7, 110.2 - 123.9 Mb), *ramosa1* (*ra1*) chr 7, 113.6 Mb, was identified as a potential target gene which might be involved in inflorescence. Additionally, at qKRN8 (chr 8, 18.8 – 20.2 Mb), we also identified *barren inflorescence1* (*bif1*), chr 8, 18.9 Mb, as a candidate KRN-gene.

As far as tillering is concerned, two candidate genes *crr1* (cytokinin response regulator1, gene model Zm00001d001865) and *arftf3* (ARF-transcription factor 3, gene model Zm00001d001879) were identified within the supporting interval of *qTil2*, on chr. 2.

Investigation of nucleotide and aminoacid sequence variation at candidate genes for ear fasciation and number of kernel rows QTLs

In order to start testing some of the candidate genes for ear fasciation and number of kernel rows, genomic sequences of B73, Lo964 and Lo1016 were recovered and compared for all the genes listed in Supp Table 2-3. At *qKRN7.1/qFas7*, we investigated the nucleotide and aminoacid difference at *ra1* (*ramosa1*). In this case, the QTL was identified in both B×L and L×L so we searched for sequence variants between B73 and Lo1016 and between Lo964 and Lo1016. However, sequence alignment showed that no difference existed between the three lines (Supp Table 3 and Supp Figure 8). Still, it might be premature to exclude possibilities that the expression levels of *ra1* have been regulated by underlying transcription factors, thus KRN being altered. Therefore, RT-PCR of this gene could be included in future studies as well.

Another KRN-influenced gene, *ct2* was found as candidate at *qFas1.2* which segregated within B×L and not in L×L. However, no sequence differences were observed between B73 and Lo1016 (while a few amino acid substitutions are predicted between Lo964 and Lo1016. See Supp Table 3 and Supp Figure 7). The same observations hold for *bgh1* a second possible candidate gene at *qFas1.2* (Supp Table 3, Supp Figure 6). Such results do not rule out *ct2* and *bgh1* as possible candidate genes at *qFas1.2*, however, their effects on ear fasciation could be due to difference in gene expression between alleles. The differences in gene expression are not currently captured by our study and they will be addressed in a future study.

Concerning *crr1*, it was identified at *qTil2* which segregated mainly with B×L, which was in accordance with sequencing results between B73 and Lo1016 where allele substitutions have been observed, as well as aminanoacid (Supp Table 3 and Supp Figure 10). Considering this correspondence, it seems deserved to arrange fine-mapping and further analysis of gene expression.

4. DISCUSSION

The inflorescence meristem originating at leaf nodes on the maize main stem is responsible for ear formation and has been recognized to play a key role in determining yield components such as number of kernels and number of kernel rows (Otegui and Bonhomme, 1998). Recently, experimental evidences accumulated suggesting that genes originally known as mutants causing fasciated ears participate to determine the number of kernel rows on the ear and therefore could impact grain yield. Indeed, mild mutations at these genes can cause modifications of the inflorescence meristem leading either to larger meristems and/or to multiple ear growing tips which in turn produce additional kernel rows (Je *et al.*, 2016; Kim *et al.*, 2022; Somssich *et al.*, 2016). However, the underlying genetic mechanisms and regulatory networks controlling the meristem size and the emergence of additional meristematic growing centers within a meristem are only partially known and therefore the exploitation of these mechanisms for plant breeding remains challenging. Therefore, the serendipitous observation of an obvious ear fasciation phenotype in the elite maize line Lo1016 (Fig. 1A) prompted us to investigate its genetic control in order to contribute useful information on the molecular genetic mechanism leading to ear fasciation and affecting an important grain yield component. A similar rationale – the observation that Lo964 is characterized by high ear prolificacy at single node (Fig. 1B) prompted us to address the genetic basis this trait.

We phenotyped ear fasciation using four approaches, namely the rate between the minor and the major cob diameters and ear ovality (these two representing cob flatness), kernel row disorder index, and an overall fasciation index, in order to capture the two different ways ear fasciation manifests, namely cob flatness and kernel disorder, as shown previously by other authors (Kim *et al.*, 2022; Mendes-Moreira *et al.*, 2015). Confirming other authors' observations, cob flatness traits and kernel row disorder correlated, and correlated with fasciation visual index. Additionally, cob flatness and kernel disorder QTL showed some level of overlap, confirming that ear fasciation manifests both as cob flatness and/or kernel row disorder. However, both the imperfect correlation between such traits (eg. r = 0.67 between

OVA and DIS) and the presence of unique QTLs for single ear-fasciation related traits (eg. *qFas1.1*, determined by ear diameters rate collected using caliper on cobs) indicated that each fasciation-related trait is a complex quantitative trait with hidden components that should not simply be expected to derive from a pleiotropic effect of a common genetic cause. In other words, at least a few genes affected kernel disorder while did not affect cob flatness, and viceversa. The presence of QTL specific for single components of ear fasciation was already observed in (Mendes-Moreira *et al.*, 2015).

Additionally, our study shed light on the relationship between ear fasciation and KRN. Confirming former studies (Je *et al.*, 2016; Kim *et al.*, 2022; Somssich *et al.*, 2016), ear fasciation positively correlated with KRN ($r = 0.51$, $P < 0.01$), and ear fasciation and KRN QTLs showed overlaps. Specifically, two out of four ear fasciation QTLs overlapped with two out of five KRN QTLs. Furthermore, at the overlapping loci, namely *qFas5-qKRN5* and *qFas7-qKRN7.1*, the direction of genetic effects for the two traits agreed with a functional positive action of ear fasciation on the number of kernel rows, as previously hypothesized or shown. A further note of interest is that at both *qFas5-qKRN5* and *qFas7-qKRN7.1* the fasciation/KRN increasing allele was provided by Lo1016, and the effect of the Lo1016 alleles at the two QTLs was detected in both B×L and L×L . In other words, at *qFas5-qKRN5* and *qFas7-qKRN7.1*, Lo1016 carries alleles increasing both ear fasciation index and kernel row number, and such positive effect of the Lo1016 allele was detected 'across' genetic backgrounds (ie. when compared with B73 and when compared with Lo964). However, the effect on KRN was detected in the L×L background only, likely because the KRN mean value in the L×L genetic background was lower than that in B×L (15.97 and 17.40 kernel rows per ear, respectively. Table 1). Indeed, in a high KRN context such as the B×L cross, any KRN -increasing allele such as the ones from Lo1016 would likely contribute just marginally to KRN increase. In L×L, the genetic effect at both QTLs for KRN was similarly estimated to be 2a = approx. 0.6 rows per locus (0.57 at *qKRN5* and 0.62 at *qKRN7.1*), equivalent to approx. 4% (0.6/16.5 rows per ear) of the average trait value in these populations (Table 1). Homozygous Lo1016 allele substitutions at both loci are therefore expected to add approx. one row per ear, therefore contributing to c. 6% (1/16.5 rows) of grain yield. While this estimate should be considered

with great caution, this notwithstanding this increase would correspond to a rather important portion of grain yield per hectare, therefore it should be considered in plant breeding programs especially when based on marker assisted selection which could target and utilize specific alleles and/or haplotypes.

A partial pleiotropy-based connection between ear fasciation and KRN (ie. genes promoting ear fasciation will eventually affect KRN) was already observed in former studies and is supported by our QTL consensus map (Fig. 4A). For example, Liu et al (Liu, Du, Huo, *et al.*, 2015) found a KRN-QTL, *qKRN5-4* between *umc1971* and *umc1071* affecting kernel row number, and mapping nearby our *qFAS5*. Additionally, (Chen *et al.*, 2019a) mapped a QTL named *KRN7.1* ranging from 21.5 Mb to 123.7 Mb on chromosome 7 in a NAM population, thereby covering the clustering region grouped by *FAS7* and *DIS7.1*. The same locus was also identified by (Brown *et al.*, 2011) in which two ear row number (ERN) QTL appear to overlap with *qFas7-qKRN7.1* identified in our study. Another example is the relationship between the large effect QTL *KRN4*, on chr 4, with the ear fasciation-like phenotypes caused by mutations in the *UNBRANCHED3* (*UB3*) gene, which negatively regulates maize kernel row number by producing abnormally shaped ears (Liu, Du, Shen, *et al.*, 2015; Du *et al.*, 2020). *KRN4* was eventually shown to be an *UB3* long-range cis regulatory element positioned ca. 60 kb downstream of *UB3* and the presence of different *KRN4* alleles in near isogenic lines results in different levels of *UB3* expression (Du *et al.*, 2020).

We also detected loci affecting the number of kernel rows independently from ear fasciation on chr 2 and chr 8 (*qKRN2* and *qKRN8*, respectively. Table 2) with kernel number increasing alleles dispersed between parental lines (from Lo964 and Lo1016, respectively). Many independent QTL mapping studies for the number of kernel rows has already been carried out and a thorough review is beyond the objectives of our study. However, it should be noted that a recent study cloned a major KRN QTL mapping on chr 2, just 10 Mb away from qKRN2 (Chen *et al.*, 2022). The gene was shown to encode for a member of the highly duplicated *WD40* gene and protein family, which play important role in diverse cellular functions like signal transduction, cell cycle control, intracellular transport, chromatin remodelling, cytoskeletal organization, and others. The authors verified that *WD40* alleles increasing the number of

kernel rows acted by increasing inflorescence meristem size, likely providing additional space for initiation of spikelet pair meristems and hence a higher number of kernel rows (Chen *et al.*, 2022). Given the close proximity (approx. 10 Mb) between *WD40* identified in Chen et al. (2022) and our QTL *qKRN2* in the subtelomeric region of chr 2, it will be certainly worth checking the effective identity/distinction between the two loci.

By cross-checking the QTL supporting intervals from our and other studies with the map positions of a number of inflorescence related candidate genes we identified a relatively short list of candidate genes possibly involved in explaining ear fasciation in the genetic background of our study, including *ramosa1* (*ra1*) (Dempewolf, 2010), *compact plant2* (*ct2*) (Bommert, Je, *et al.*, 2013), *big grain1 homolog1* (*bgh1*) (Simmons *et al.*, 2020), *barren inflorescence1* (*bif1*) (Barazesh and McSteen, 2008) etc (Fig. 4, Supp Table 2). The maize historical tassel and ear mutant *ra1*, encoding a zinc-finger transcriptional factor and producing ear and tassel with increased branches (Kim *et al.*, 2022) maps only 0.5 Mb away from the QTL cluster region including *qFas7*, and within the QTL supporting interval of *qKRN7.1*, thus *ra1* should be considered a very strong candidate gene to our *qFas7-qKRN7.1* QTL. This QTL region also appeared a hot region for ear fasciation and KRN, since many other authors mapped QTLs for these traits in this region (Fig. 4A). Due to artificial selection for thousands of years on ear shape (Sigmon and Vollbrecht, 2010), *ra1* is very poor of genetic diversity. However, ear formation is likely to be influenced by alteration in expression of *ra1*. For example, Liu et al (Liu *et al.*, 2019) found that *rel2* encoding a transcriptional co-repressor could dramatically increase the formation of long branches in ears of both *ra1* and *ra2* mutants. Comparison of genomic sequences between our three parental lines clearly showed lack of nucleotide sequence variation at *ra1* (Supp Figure 8). However, as shown in many studies, QTL are often due to allelic variation in gene expression level of the causative gene rather than from variation of coding allelic sequences (Salvi and Tuberosa, 2005; Jaganathan *et al.*, 2020), therefore, quantification of the expression of *ra1* in the ear primordium of Lo1016 and Lo964 will enable to test *ra1* involvement in ear fasciation driven by *qFas7*. Interestingly, *ra1* is not the only candidate gene mapping at *qFas7*, and other gene models, such as *Zm00001d020486* and *Zm00001d020461* due to their high expression level on ear inflorescence (Stelpflug *et al.*, 2016)

and inferred transferase activity of their orthologues in rice with relatively high FPKM in ear primordium will be considered for expression analysis such as thus requiring fine-mapping and analysis of expression levels.

Two potentially strong candidate genes, *compact plant2* (*ct2*) and *Big grain homolog1* (*bgh1*) were also identified within the supporting interval of *qFas1.2*. Maize lines carrying mutations at *ct2* produced fasciated ears (Bommert, Je, *et al.*, 2013), and the overexpression of *bgh1* resulted in increased ear kernel row number and total ear kernel number and mass, whereas individual kernels tended to developed slightly smaller (Zhang *et al.*, 2022), showing similar phenotypes of its rice ortholog *BG1* whose overexpression leads to significantly increased grain size (Liu, Tong, Xiao, *et al.*, 2015). Five common native *bgh1* alleles exhibit little structural and expression variation compared to the large increased expression conferred by these ectopic alleles (Simmons *et al.*, 2020). Distinct from the situation of *ra1*, preliminary analysis of sequencing data of three parent lines showed indel and substitution mutations in nucleotide and protein sequences of *ct2* and *bgh1* between Lo964 and Lo1016, however, no difference between B73 and Lo1016 coding sequences were observed, which is the genetic background where the QTL was detected (Table 2; Suppl Table 3). Thus also for this QTL, and for *ct2* and *bgh1*, we have to hypothesize either a difference in expression levels between the two alleles caused by variation at cis-regulatory elements or the presence in *qFas1.2* of other potential candidate genes affecting proliferation of ear primordium eventually causing ear fasciation.

In our study we dealt with ear prolificacy at single node, whereas other types of ear prolificacy include multi-stem/tillering, and multi-node prolificacy (Wang *et al.*, 2021). Single node ear prolificacy is clearly an architectural trait little investigated across maize genetics. At the same time, it is expected that the three types of ear prolificacy will likely require overlapping cell and tissue functions and therefore overlapping genes controlling them, suggesting the molecular genetics studies focusing on one single type of ear prolificacy will shed light on mechanisms acting also on the other types.

We noted in Introduction that ear prolificacy at the same node is due to the development of axillary buds at shank nodes/leaves (Ortez *et al.*, 2022). Variation in the number of ears at

the same node between maize genotypes could then be explained by a different level of apical dominance played by the main ear developing at the tip of the shank. Indeed, this is the typical explanation used to explain different numbers of ears at different node of the main plant stem between maize genotypes where the inhibitory effect on the activity of axillary buds below the tassel and the top ear is caused by basipetal transporting of indole-3-acetic acid in stems (Domagalska and Leyser, 2011). This would prevent underground axillary meristems to develop into tillers, and aboveground meristems to grow more ears in maize. However, whether this mechanism is acting on the ear shank to control ear prolificacy at single node has yet to be proved. In our study, four major QTL involved in prolificacy were mapped (Table 2; Fig. 3 and Supp Fig. 4 and 5). An overlap was observed between our *qProl4* and *prol4.1* by Wills (Wills *et al.*, 2013), despite no association with known genes inside this interval was established.

This notwithstanding, it is worth reporting that the gene *barren stalk fastigiate1* (*baf1*), a known gene that when mutated produces no ear shoots (Zhou *et al.*, 2021) maps very close to the north border of *qProl9* (Fig. 4B). Because of the known approximation behind QTL mapping, it is certainly worth carrying out further investigation on the possible connection between *baf1* and *qProl9*. Additionally, it is proved that *teosinte branched1* (*tb1*) does not only produce tassel-like ear branches, but also inhibits axillary bud growth as a repressor (Dong *et al.*, 2017).

More generally, it is well known how maize domestication proceeded from teosinte by suppressing the development of axillary branches by a profound increase in apical dominance. The teosinte plant has multiple long lateral branches, each tipped with a tassel. At each node along these lateral branches, there are clusters of several small ears. Summed over all branches, a single teosinte plant can easily have more than 100 small ears. By comparison, the maize plant has relatively few lateral branches (ie the two ear shanks), each tipped by a single large ear (in teosinte it would be a tassel) (Wills *et al.*, 2013). Using a set of 866 maize-teosinte BC2S3 recombinant inbred lines, Wills et al (2013) mapped eight ear prolificacy QTL, distributed across the first 5 chromosomes. One QTL on chromosome 1 (*prol1.1*) showed a much larger effect and accounted for 36.7% of the phenotypic variance. This QTL was shown to correspond to *grassy tillers1* (*gt1*) gene, which encodes a homeodomain leucine zipper

transcription factor. This information is crucial to begin understanding the regulatory mechanisms behind shoot branching in maize, and towards understanding the molecular genetic basis behind our *qProl* QTLs.

It is thought that tillering is highly related to the morphology and habit of growth of the perennial herbage grasses (Jewiss, 1972), with high scientific and application values. For example, tillering in rice (*Oryza sativa L.*) enables to improve grain production and is recognized as a model system for the study of branching in monocotyledonous plants (Li *et al.*, 2003). And Min et al (Xu *et al.*, 2005) identified a putative auxin efflux carrier, *OsPIN1* in rice, and either overexpression or inhibition of this gene in mutants influenced tiller numbers and shoot/root ratio. Studies of tillering in wheat (*Triticum aestivum* L.) have been also carried out for decades. However, compared with those two crops, a fewer number of studies addressed tillering in maize. In our study we mapped four TIL-associated QTL distributed on chromosome 1, 2, 4, and 9, mainly from the joint population. The negative additive effects of *qTil1*, *qTil4* and *qTil9* indicated major contribution of alleles of Lo1016, in line with the phenotype of three parent lines (Lo1016 is the only parent showing some tillering when grown in the field in standard conditions). However, the fact that the additive effects of *qTil2* is contributed by the B73 allele is apparently in contradiction with the observation that B73 develops virtually no tillers at least in our field conditions (Table 1). This observation suggests that at least some level of gene interaction occurs between tillering loci in our genetic materials, which should be subjected to future investigations.

Finally, it should be noted that while shoot branching producing ears and tillering clearly share developmental similarities (eg. both branching types originate from axillary buds of the stem nodes), in our study we did not find phenotypic correlation between ear prolificacy at single node and tillering (Fig. 2, Supp Fig. 1 and 2). Additionally, we did not find any overlaps between QTLs of the two traits. The most likely explanation is the specific genetic architecture of the genes involved in controlling the two traits in our genetic background. In other words, although it is likely that at least some genes in maize control the two traits with some pleiotropic effect, in our genetic background those genes did not segregate. Another factor, partially connected with this, is that the parental line contributing ear prolificacy (Lo964) showed

virtually no tillering, and the parental line contributing high tillering (Lo1016) showed no ear prolificacy, suggesting that each parental line possibly contributed in the segregating population strong (or relatively strong) alleles at gene acting only on one of the two traits.

5. CONCLUSION

In this study, a joint population consisting of 165 RIL lines developed starting from two experimental crosses with a parental line (source of ear fasciation) in common was utilized for the genetic dissection of ear fasciation, KRN, ear prolificacy and tillering. We identified solid positive correlation between ear fasciation and KRN, and provided evidence that the correlation was partially due to the pleiotropic effects of genes inducing inflorescence meristem fasciation at loci on chr 2 and chr 7. The fasciation effect of single ear fasciation QTL was mild and this likely contributed a positive effect on kernel row number, since it is well known that highly misshapen ears produced by plants carrying strong mutations at inflorescence meristem genes carry fewer kernel row numbers. We showed that our ear fasciation QTLs overlap with other fasciation and/or KRN QTL, which suggests that the genetic control of fasciation is not tremendously complex. Candidate genes were identified and alleles were compared between the three parental lines. However, we did not identify so far functional nucleotide polymorphism enabling to explain the strong phenotypic effects on fasciation and/or KRN observed, suggesting either that the selected candidate genes have nothing to do with fasciation or that functional variation lies in gene expression variation rather than nucleotide or amino acid variation.

Analysis for ear prolificacy at single node enabled us to identify four QTLs, of which one (on chr. 4) perfectly overlapped with an ear prolificacy identified in a former study in a maize × teosinte cross. The other three QTL mapped in novel chromosome regions previously unknown to control this trait. Quite unexpectedly, we did not find correlation and QTL map overlaps between ear prolificacy and tillering, although the two traits share obvious developmental basis. The genetic architecture of the trait in this specific genetic background likely cause the lack of correlation and QTL overlaps. Overall, our study provided clear entry

points for the molecular dissection of important yield component traits, which should help both developing molecular markers for marker-assisted selection to be deployed in breeding programs and starting the procedures leading to cloning the genes underpinning the here described QTLs.

Some notable co-localizations between our QTLs and known functional genes, such as qFas7 – qKRN7.1 and ramosa1, were observed in our result datasets, in spite of the modest effects of QTLs compared with the potentially stronger effects of genes around. Thus, our results are in line with the so-called Robertson's hypothesis (Robertson 1985) which hypothesized that a QTL can be generated by a minor mutant allele at a Mendelian locus known thanks to the presence and the former characterization of major mutant allele(s). This hypothesis was extended by Schnable et al. (Schnable and Freeling 2011), who suggested that strong-effect QTLs should most frequently correspond to syntenic genes, whereas weaker-effect QTLs should correspond to non-syntenic ones, such as the genes identified in Tai et al. (Tai et al. 2016). In hence, the latter ones are usually regarded as regulation factors (or modifiers) of functional genes, such as ramosa1 enhancer locus2 (rel2) positioned on chromosome 10 (Gallavotti et al. 2010). For instance, rel2 mutants can dramatically increase the formation of long branches in ears of both ra1 and ra2 mutants (Liu et al. 2019), suggesting the upregulation role in the ramosa pathway.

Acknowledgement

Time flies away so fast before realizing. It seems that I might stay in Italy, enjoy coffee and pizza, watch Seire A as if I were doing in the past four years. Honestly, these four years do affect my lifestyle and life attitude deeply. For example, I started taking short trips with friends during weekends gradually rather than just staying at home. Or, I have tried to made some Italian food by myself rather than only tasting Chinese food. What I learned during these years is that it is not worth filling your life only with work. It is better to improve your quality of life by enjoying something interesting, like delicious food, beautiful travelling and so on.

Of course, I must express my gratitude to my colleagues. They really did a lot of things to help me, not only on studies, but also on living.

Thanks to Alberto. I would remember the time when we worked in the maize filed to do the selfing and shovelomics forever. And after coming back to the greenhouse, you also helped me to deal with some tiny but annoying stuff.

Thanks to Serena. You are so kind for everything, I have to say. I am really sorry to disturb you to help me call Italian number for everything. Besides, your work contributing to SNP calling improved this thesis a lot.

Thanks to Christian. Your rich experience on gene expression and sequencing did help me overcome a lot of difficulties, and improve the efficiency a lot.

Who I want to thank a lot are Prof. Silvio. He is a real gentleman and glad to help others. When I got in difficulties, related to unibo stuff for example, he always sent an email or call the number to make it clear. Additionally, he is a good friend in life. We are always chatting on something interesting.

Also, thanks to my familes although I could not see them due to the pandemic, which makes me miss them a lot. And I really accompany with them for some time.

In the end, I would say, I do appreciate the experience in this lab. I do appreciate the viewing in this country. Wish I could visit Italy again in future!

[a]) Actual population (B×L, L×L or JP, with JP indicating the two populations jointly analyzed for QTL using the command 'NAM' in QTL Icimapping.

[b]) QTL peak position in cM in the specific linkage map (B×L, L×L or JP, from this study)

[c]) Peak LOD value from Composite Interval Mapping.

[d]) PVE = Proportion of phenotypic variance explained.

[e]) Peak LOD value of the single population B×L when analysed as JP. Sub-significant relevant LOD score are in Italics.

[f]) Peak LOD value of the single population L×L when analysed as JP. Sub-significant relevant LOD score are in Italics.

[g]) QTL additive effect express as 2a = (mean homozygous B73 – mean homozygous Lo1016). Additive values related with sub-significant LOD scores are in Italics.

[h]) QTL additive effect express as 2a = (mean homozygous Lo964 – mean homozygous Lo1016). Additive values related with sub-significant LOD scores are in Italics.

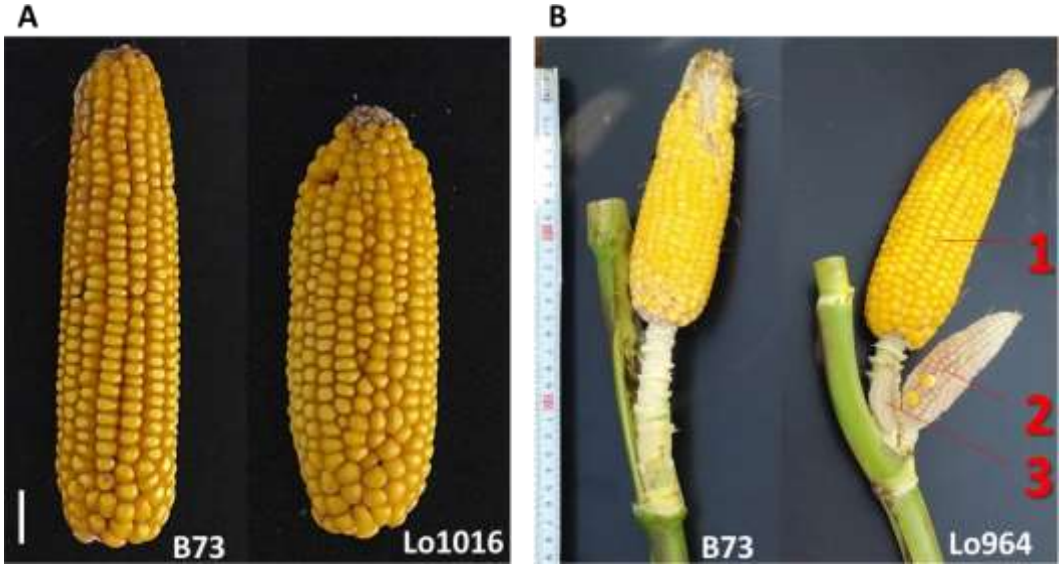

Figure 1. Target ear traits analyzed in this study. (A) Representative images of the ear-fasciation phenotype observed in Lo1016 (B73 is shown as comparison). White line, 10cm. (B) Representative images of the ear prolificacy phenotype at top ear-bearing node as observed in Lo964 (B73 is shown as comparison).

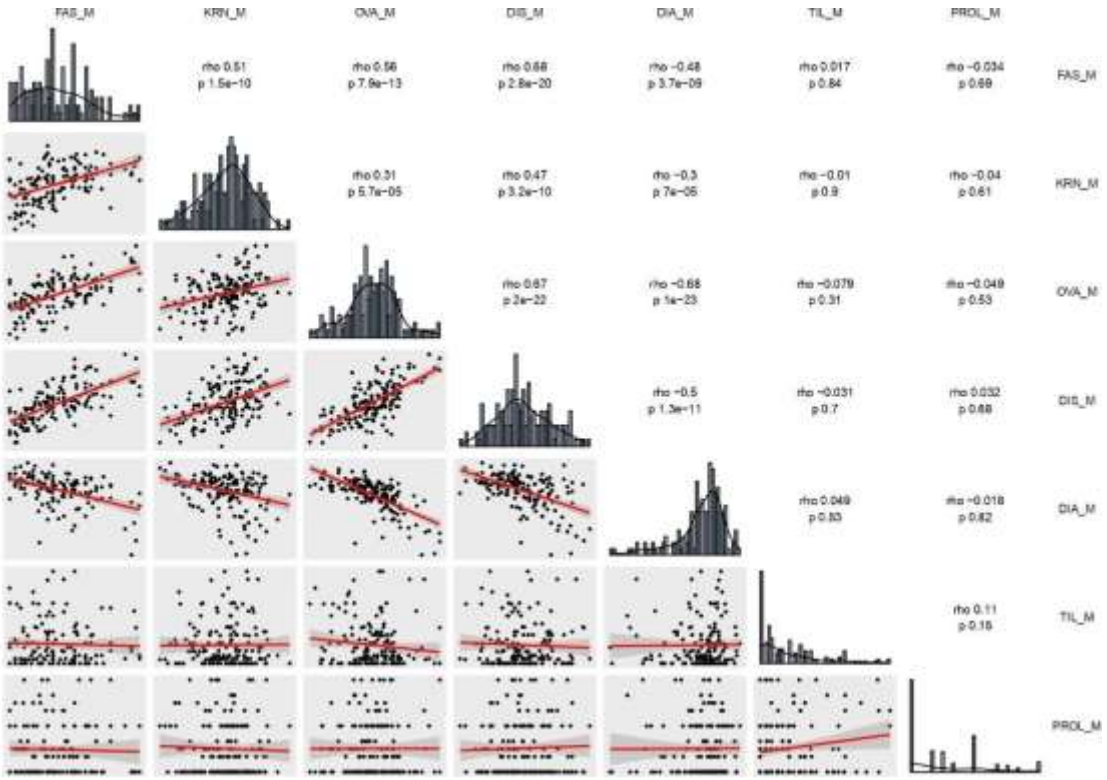

Figure 2. Distribution frequency histograms of, and correlation (Spearman) among all traits estimated on the two RILs (B×L and L×L) combined.

The upper right part presents all correlation indexes (*rho*, thus the upper number) and corresponding significant levels (*p*, thus the lower number). Minus rho values show negative correlation between two traits, and vice versa. The lower left part presents scatter plots and fitter curve (the red line inside) between two traits. The diagonal shows histogram charts of each trait. DIA (ear diameters rate), DIS (kernel row disorder), OVA (ear ovality), FAS (ear fasciation index), KRN (kernel row number), PROL (prolificacy), TIL (number of tillers), M, mean value.

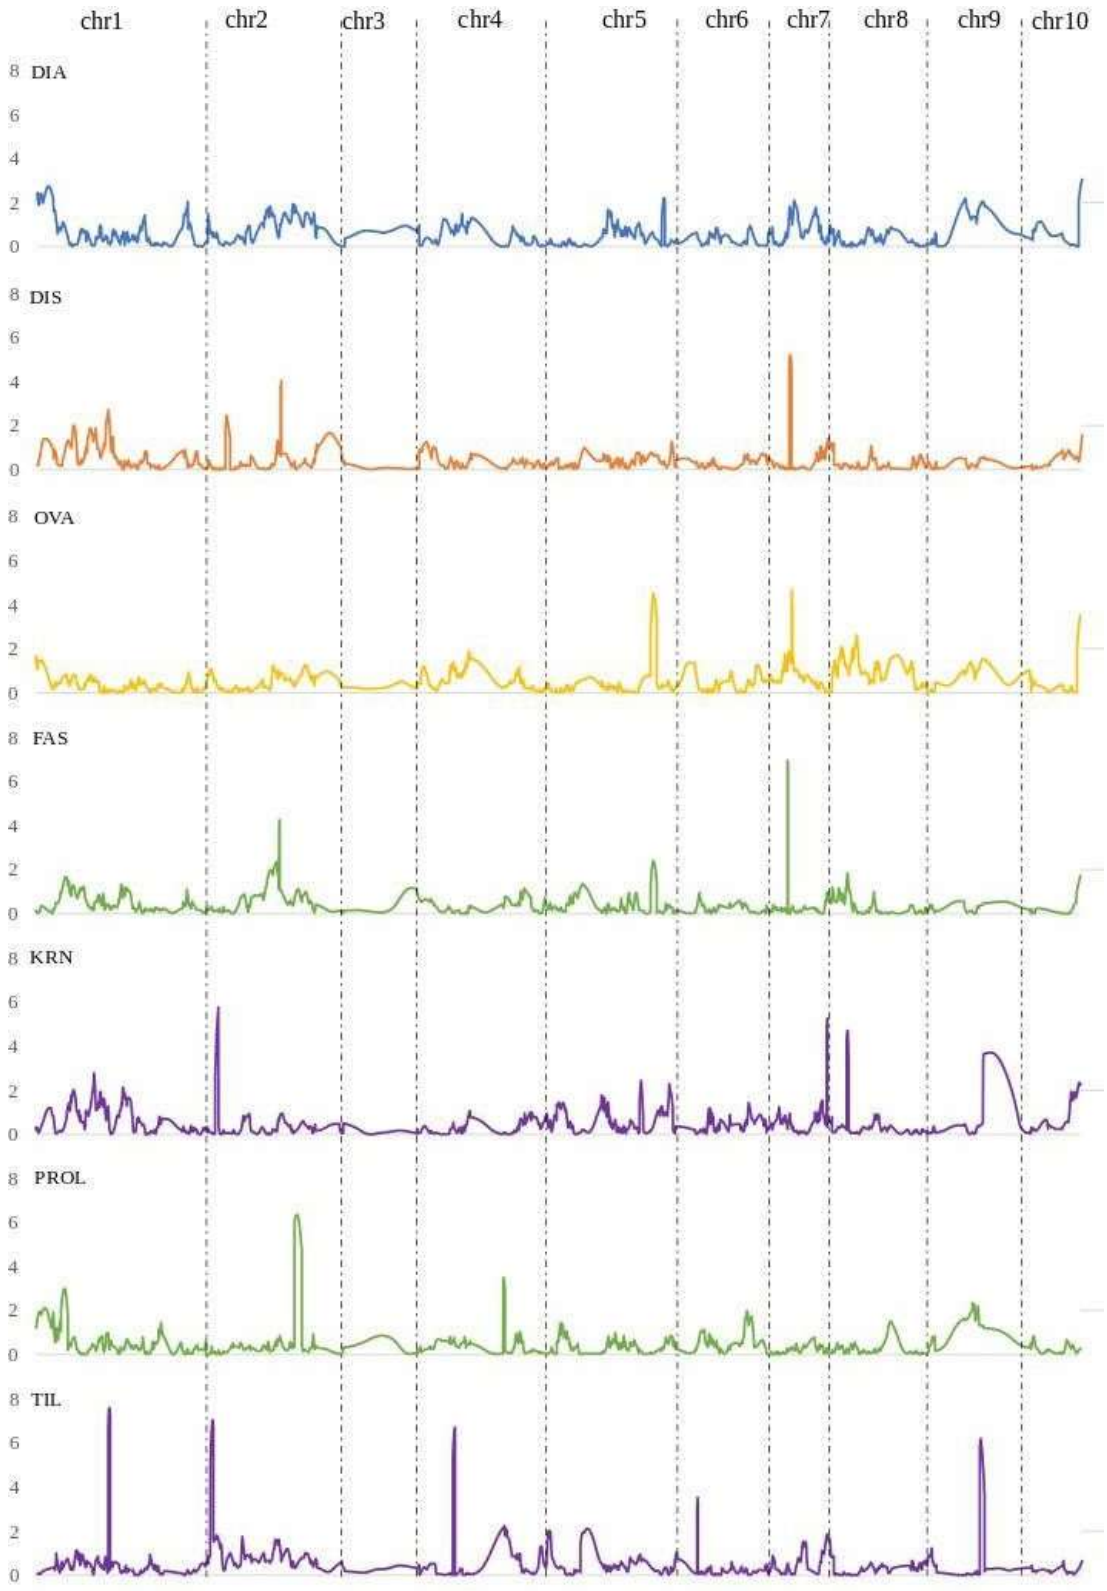

Figure 3. QTL LOD profiles obtained by the joint analysis of the two RIL populations B×L and L×L, for DIA (ear diameters rate), DIS (kernel row disorder), OVA (ear ovality), FAS (ear fasciation index), KRN (kernel row number), PROL (prolificacy), TIL (number of tillers).

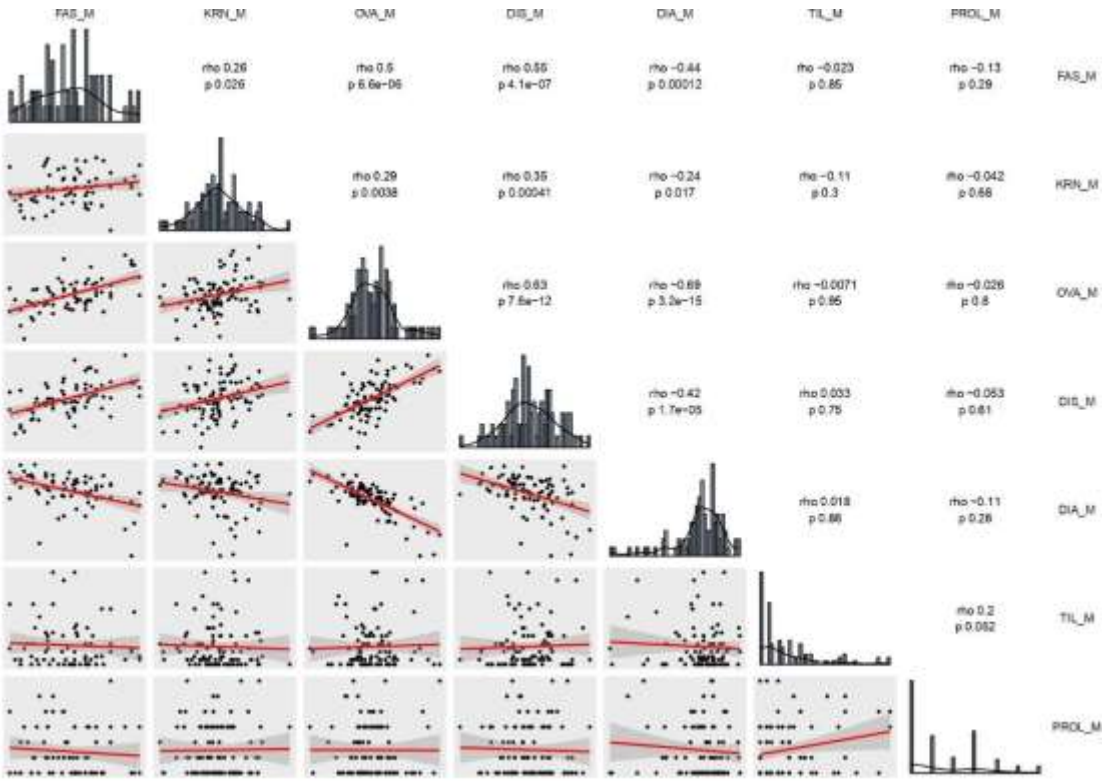
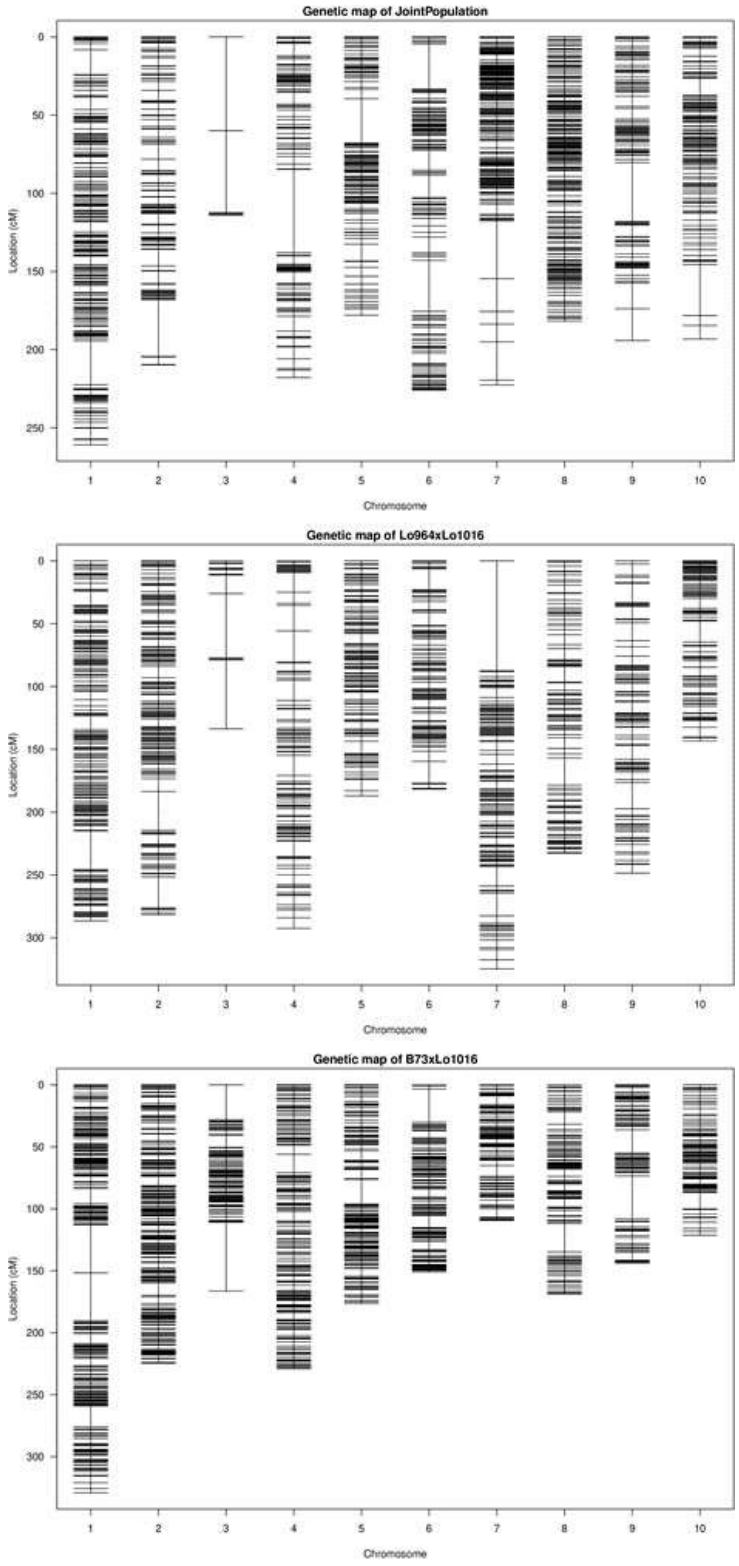
Supplementary Figure 1. Distribution frequency histograms of, and correlation (Spearman) among all traits estimated on the B×L.

The upper right part presents all correlation indexes (*rho*, thus the upper number) and corresponding significant levels (*p*, thus the lower number). Minus rho values show negative correlation between two traits, and vice versa. The lower left part presents scatter plots and fitter curve (the red line inside) between two traits. The diagonal shows histogram charts of each trait. DIA (ear diameters rate), DIS (kernel row disorder), OVA (ear ovality), FAS (ear fasciation index), KRN (kernel row number), PROL (prolificacy), TIL (number of tillers), M, mean value.

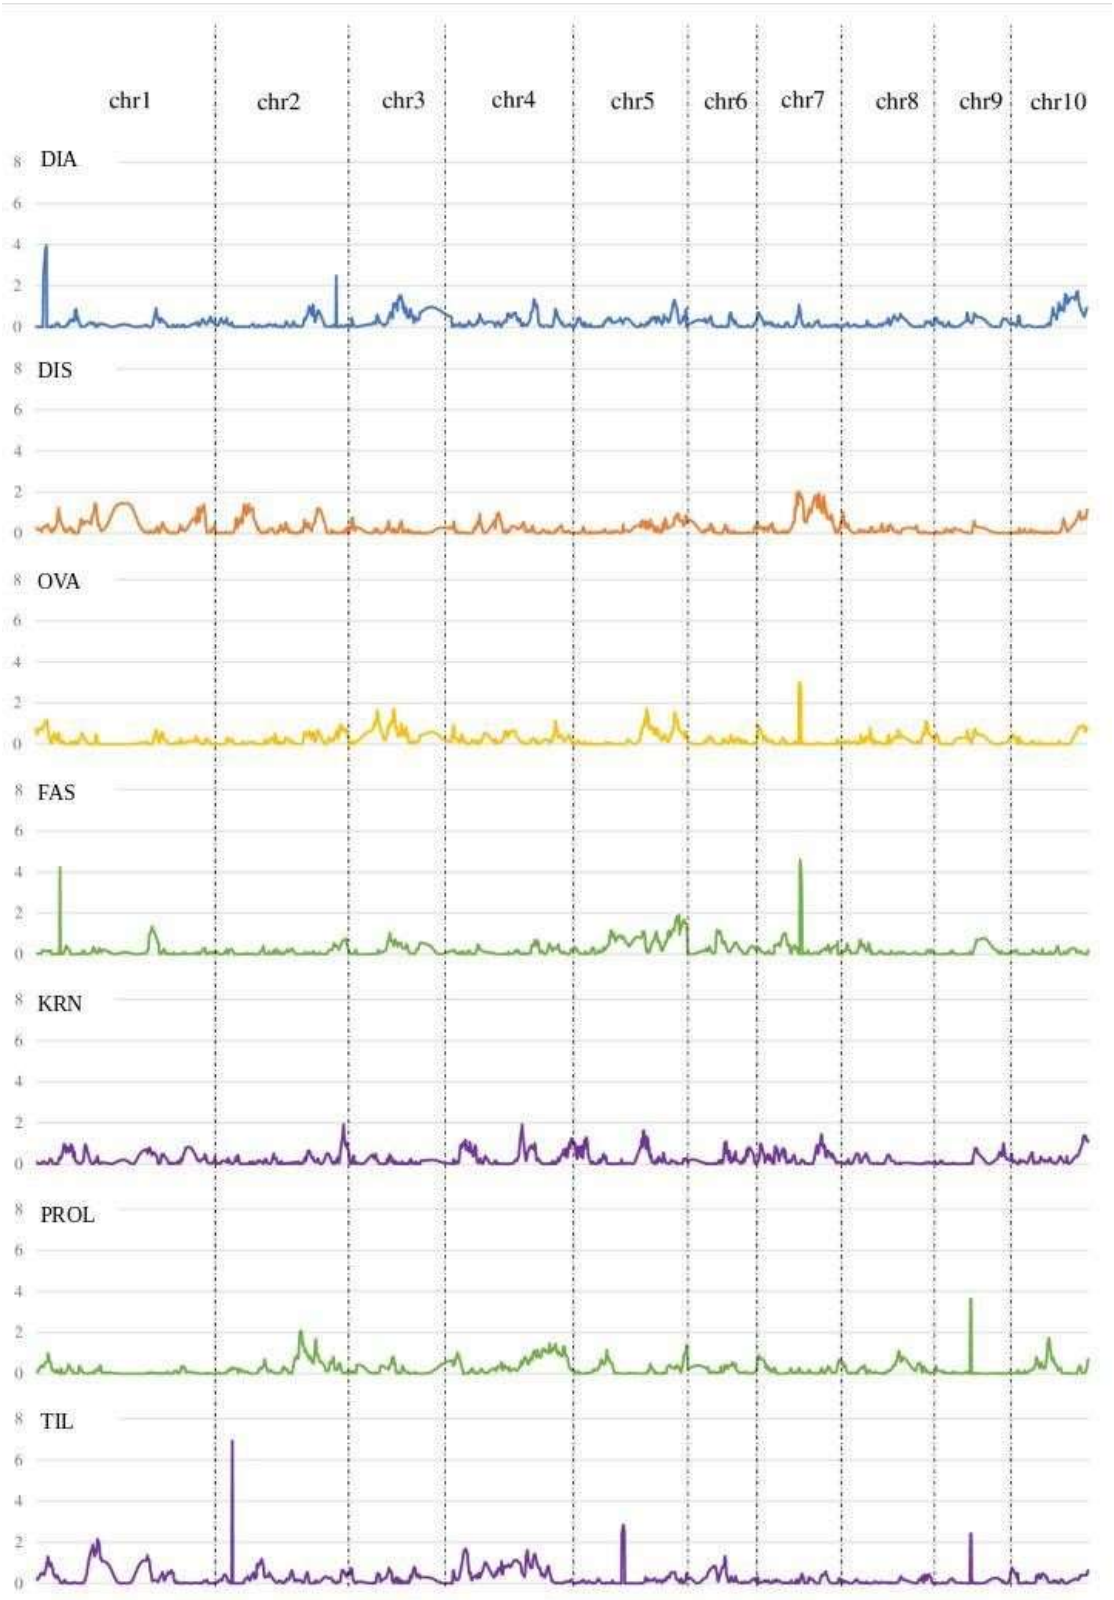


Supplementary Figure 2. Distribution frequency histograms of, and correlation (Spearman) among all traits estimated on the L×L.

The upper right part presents all correlation indexes (*rho*, thus the upper number) and corresponding significant levels (*p*, thus the lower number). Minus rho values show negative correlation between two traits, and vice versa. The lower left part presents scatter plots and fitter curve (the red line inside) between two traits. The diagonal shows histogram charts of each trait. DIA (ear diameters rate), DIS (kernel row disorder), OVA (ear ovality), FAS (ear fasciation index), KRN (kernel row number), PROL (prolificacy), TIL (number of tillers), M, mean value.



Supplementary Figure 3. Linkage map plot. From top to bottom: JP, L×L, B×L



Supplementary Figure 4. QTL LOD profiles obtained by B×L, for DIA (ear diameters rate), DIS (kernel row disorder), OVA (ear ovality), FAS (ear fasciation index), KRN (kernel row number), PROL (prolificacy), TIL (number of tillers).

Supplementary Figure 5. QTL LOD profiles obtained by L×L, for DIA (ear diameters rate), DIS (kernel row disorder), OVA (ear ovality), FAS (ear fasciation index), KRN (kernel row number), PROL (prolificacy), TIL (number of tillers).
