ABSTRACT

Leber's hereditary optic neuropathy (LHON) is due in 90% of cases to three common point mutations affecting complex I subunit genes encoded by the mitochondrial genome (mtDNA). Besides these common mutations, there is a long and complex list of other mutations involved at various levels in the pathogenesis of LHON. On this scenario, we here report for the first time on the existence of LHON associated with peculiar combinations of individually non-pathogenic missense mtDNA variants, affecting the MT-ND4, MT-ND4L and MT-ND6 subunit genes of Complex I. The pathogenic potential of these mtDNA haplotypes is supported by multiple evidences: first, the LHON phenotype is strictly inherited along the maternal line in one very large family; second, the combinations of mtDNA variants are unique to the maternal lineages characterized by the recurrence of LHON; third, the Complex I-dependent respiratory and oxidative phosphorylation defect is co-transferred from the proband's fibroblasts into the cybrid cell model. Finally, all but one of these missense mtDNA variants clustered along the same predicted fourth E-channel deputed to proton translocation within the transmembrane domain of Complex I, involving the ND1, ND4L and ND6 subunits.

Hence, the definition of the pathogenic role of a specific mtDNA mutation becomes blurrier than ever and only an accurate evaluation of mitogenome sequence variation data from the general population, combined with functional analyses using the cybrid cell model, may lead to final validation. Our study conclusively shows that even in the absence of a clearly established LHON primary mutation, unprecedented combinations of missense mtDNA variants, individually known as polymorphisms, may lead to reduced OXPHOS efficiency sufficient to trigger LHON.

With this complexity in mind, mtDNA genetic variation itself may play a modifying role in LHON. Many studies reported the association of LHON and a specific mitochondrial haplogroup classified as J. Here we present the largest sequence survey of the entire mtDNA ever performed assessing 119 independent probands from all Europe carrying the m.14484T>C/MT-ND6 mutation. Besides the occasional finding of double mutants, we confirm the association with the haplogroup J root, but not with its more recent sub-clades. The phylogenetic analysis suggests a possible double role of this haplogroup: it may act as predisposing factor to mutagenesis at m.14484T position, or preserving the pathogenic

mutation during evolution. On the clinical ground, the penetrance of LHON due to m.14484T>C/MT-ND6 mutation increases on the haplogroup J background, especially in females, and multiple founder haplogroup J events can be recognized in our cohort.

Considering the strong association of mtDNA haplogroups with LHON, we also investigated if a similar association may act on Dominant Optic Atrophy (DOA). This is another inherited optic neuropathy similar to LHON, caused by mutations in the OPA1 gene, which encodes for a protein essential for mitochondrial fusion and mitochondrial homeostasis. Our results indicated that the relationship of DOA with mtDNA genetic variation is complex: no specific haplogroups resulted strongly associated with DOA, neither clearly modified its clinical outcome. We only documented a minor effect of the mitogenome variation in DOA, in particular when compared with what it seems a definitely stronger role as modifier played by nDNA.

INTRODUCTION

Mitochondria: origin, structure and functions

Mitochondria are unusual organelles. They primarily act as the powerhouse of the cell, but they are also involved in programmed cell death, calcium homeostasis and several biosynthetic pathways. They are wrapped by two membranes, they have their own genome, an independent protein synthesis apparatus, and can change their shape to adapt to the different metabolic needs of the cell, from discrete isolated organelles to a large network.

Their origin, according to the endosymbiotic theory, was due to the increasingly oxygen-rich atmosphere and the primordial eukaryotic cell, unable to metabolize oxygen, acquired bacteria much better adapted to oxygen (Sagan, 1967; DiMauro et al., 2013).

The mitochondrial genome (mtDNA) is present in multiple copies and codes for a few fundamental protein components of the oxidative phosphorylation (OXPHOS) (Anderson et al., 1981).

The mitochondrial double-membrane is composed by the outer (OM) and inner (IM) membranes, this latter separating the inner membrane space (IMS) from the internal matrix. The OM has similar composition to the cell membrane; many transport channels (porin) are present and make the OM permeable to molecules of 5000 dalton or less (ions and small proteins). Differently, the IM contains high levels of cardiolipin, making it especially impermeable to ions, and selective transport proteins are needed to transport the molecules necessary to matrix enzymes or their metabolites. This membrane is fundamental for maintenance of an electrochemical gradient between the matrix and the IMS (Frey and Mannella, 2000). The IM is also organized in *cristae*, which can shift from tubular to lamellar structures, depending on the conformational state (Frey and Mannella, 2000). All *cristae* connect to the inner boundary membrane via a tubular structure, named *crista* junctions, that limits diffusion between the intracristal space and the intermembrane space (Frey and Mannella, 2000; Rampelt et al., 2017). *Cristae* are the specialized compartment for the respiratory chain complexes and the ATP synthase (Rampelt et al., 2017).

The fundamental mitochondrial function is energy conservation, in the form of ATP molecule, synthesized by the OXPHOS metabolism. Furthermore, other pathways take place in mitochondria: partial synthesis of steroids, heme-groups synthesis, Ca^{++} intracellular

homeostasis, reactive oxygen species (ROS) production and detoxification and apoptosis regulation.

Oxidative Phosphorylation

OXPHOS is the final step of cellular respiration and is a two-phases biochemical process: electron transport chain, with NADH and FADH₂ redox to generate a proton gradient, and ATP synthesis, exploiting the proton gradient. The OXPHOS uses the electrons flow that are transported through a series of protein complexes, which are embedded in the lipid bilayer of the mitochondrial IM, to provide most of cellular energy in the form of ATP (Balaban, 1990; Friedman and Nunnari, 2014).

The OXPHOS system is composed of five multimeric enzymatic complexes (CI-V) and consists of 87 subunits, 13 directly encoded by the mitochondrial DNA (mtDNA) (Figure 1).

Figure 1. Mitochondrial respiratory chain (Schon et al., 2012)

All complexes are integrated in the lipid bilayer of the mitochondrial IM and together with two mobile electron carriers, ubiquinone (CoQ) and cytochrome c (cyt c), they make up the electron transport chain. The electron transport is coupled to the generation of a proton gradient across the IM and this is used by complex V to synthesize ATP from ADP (Mitchell, 1961). The electron carriers, nicotinamide adenine dinucleotide (NADH) and flavin adenine dinucleotide (FADH₂), are reduced during the Krebs cycle or the β -oxidation of fatty acids.

CI is the largest respiratory complexes, comprising 45 subunits, only seven mitochondrially encoded (Fiedorczuk et al., 2016). It's a L-shape structure protein, with two major domains: the hydrophilic matrix arm comprises flavin, involved in electron transfer, and the membrane arm, involved in proton translocation (Fiedorczuk et al., 2016). The electrons are transported

via iron/sulphur clusters to CoQ, reduced to CoQH₂ (Fiedorczuk et al., 2016), with the simultaneous translocation of four protons across the IM into the inner membrane space.

CII is formed by four subunits, completely encoded by the nucleus, and catalyzes the oxidation of succinate to fumarate. Reduced CoQ can move and transport the electrons to CIII (ubiquinone-cytochrome c oxidoreductase) (Lancaster and Kröger, 2000). CIII is a functional dimer and transfers electrons from CoQH₂ to cytochrome c, that donates electrons to complex IV through IMS (Darrouzet et al., 2001; Dibrova et al., 2013).

CIV is the terminal enzyme of the respiratory chain, composed of 13 subunits, of which three are encoded by the mtDNA. This complex reduces O₂ to H₂O, translocating protons from matrix to IMS. During the electron transfer, the energy released enables the proton pumping against gradient from the matrix to the IMS. The proton transfer occurs only in CI, III and IV. The electrochemical gradient, positive outside and negative inside the IM, is used by complex V (ATP synthase) to synthesize ATP.

CV consists of two major functional domains, a large extra-membranous portion (F₁) sector and a membrane-intrinsic portion (F₀) sector joined together by central and peripheral stalks (Walker, 2013). CV has two subunits encoded by mtDNA (MT-ATP6 and MT-ATP8), which take part to the membrane-bound portion (F₀) of the complex, and about 13 other subunits encoded by nDNA (Abrahams et al., 1994). Protons from the intermembrane space enter CV through the F₀ complex leading to the rotation of the catalytic complex. The rotational energy of the motor is transmitted to the catalytic domain by the central stalk, which is attached directly to the rotary motor, and then used for ATP synthesis (Walker, 2013). ATP formation requires a sufficient supply of ADP and phosphate, and specific carriers transport both substrates across the mitochondrial membranes: the adenine nucleotide translocator (ANT) and the phosphate carrier (Seelert and Dencher, 2011).

Morphology

Mitochondria appear as a dynamic network in balance between the processes of fusion and fission of both OM and IM (Chan, 2012; Liu et al., 2009). During fusion the membranes of two discrete mitochondria merge, uniting and mixing their content. Opposite, during fission a single mitochondrion splits into two organelles. Continuous rounds of fusion and fission are necessary to maintain mitochondrial homeostasis (Chan, 2012), in particular to meet the

energetic needs (Gomes et al., 2011; Mishra et al., 2014). A wide mitochondrial network is present in metabolically active cells and acts electrically as a unique system able to transmit mitochondrial membrane potential, allowing energy distribution and dissipation (Skulachev, 2001).

A “mitochondria-shaping” machinery, including both pro-fusion and pro-fission proteins, is involved in a dynamic control of the mitochondrial network, to efficiently maintain the mitochondrial population. During mitochondrial fission, the dynamin protein Drp1 is recruited from cytosol to the mitochondrial surface, self-assembles into ring-like oligomeric structures that encircle and pinch the outer mitochondrial membrane at sites of fission (Lee et al., 2017). Drp1 is essential for mitochondrial fission provoked by events like mitosis or stress, and for development of the nervous system (Ishihara et al., 2009; Wakabayashi et al., 2009). Drp1 is recruited at the mitochondrial surface by integral OM proteins (Fis1, Mff, MiD49 and MiD51). In mammals Fis1 can directly bind Drp1, although in yeast the recruitment requires Fis1 and the two WD40-containing adaptors (Griffin et al., 2005; Wells et al., 2007). Moreover, in mammals three other receptor proteins involved in fission events are reported: Mff, MiD49 and MiD51 (Losón et al., 2013; Otera et al., 2005). Mitochondrial fission plays a key role in both cell life and death. Fission occurs in the programmed cell death pathway (apoptosis), before the release of cytochrome c and caspase activation (Youle and Karbowski, 2005), and in cellular division, for correct distribution of mitochondria to daughter cells (Kashatus et al., 2011). Fission carries out a key role in mitophagy, because interruption of fission reduces the efficiency of mitophagy, suggesting that fission segregates mitochondria with loss of membrane potential (Frank et al., 2012; Stotland and Gottlieb, 2015).

Fusion is the reverse process of fission, when the inner and outer membranes of one mitochondrion melt with the respective membranes of another organelle. First, the OMs fuse, allowing the IMs to come into proximity for their fusion. In mammals, three proteins carry out this event: the mitofusins MFN1 and MFN2 for the OM fusion and OPA1 for the IM fusion (Chan, 2012). These proteins belong to the dynamin-like protein superfamily and contain GTPase activity essential for their functions (Praefcke and McMahon, 2004). MFN1 is essential to induce OM fusion, whereas the role of MFN2 is less defined. MFN2 can form hetero-oligomers with MFN1 and is suggested to participate in later steps of mitochondrial fusion (Ishihara et al., 2004; Koshiba et al., 2004). MFN2 has been shown to be involved also in

endoplasmic reticulum interactions, bridging the two organelles close at the level of mitochondrial associated membranes (MAMs), and the levels of MFN2 correlate with the oxidative metabolism of skeletal muscle (Bach et al., 2003; de Brito and Scorrano, 2008). OPA1 is essential for IM fusion, but it is also involved in shaping the cristae morphology, OXPHOS efficiency, and mtDNA maintenance (Belenguer and Pellegrini, 2013; Vidoni et al., 2013). OPA1 oligomerization, tightening cristae junctions, also controls the propensity to apoptosis by sequestering cytochrome c within the cristae and regulating its release in the IMS (Dotto et al., 2017; Frezza et al., 2006; Olichon et al., 2003). Fusion is important also for mitochondrial calcium homeostasis (Szabadkai et al., 2006), embryonic development (Chen et al., 2003), spermatogenesis and mtDNA maintenance (Chen et al., 2007).

The mitochondrial genome: mtDNA

The human mitochondrial genome (mtDNA) is a circular double-stranded molecule of about 16.6 kb, localized in the mitochondrial matrix, and represents 0,5-1% of the entire human genome. The mtDNA is present in multiple copies, ranging from tens to thousand per cell, according to the cell type. The two strands of mtDNA can be distinguished into 'heavy strand' (H-strand) and 'light strand' (L-strand), based on their nucleotide (GC) content (Fernández-Silva et al., 2003). The mtDNA is very compact, having none or only a few noncoding bases between genes and lacking in many cases the termination codons; termination is post-transcriptionally induced by polyadenylation of mRNAs (Anderson et al., 1981; Andrews et al., 1999).

The mtDNA encodes for 37 genes: 24 genes (22 tRNAs and 2 rRNAs, 12S and 16S) are necessary for transcription of 13 OXPHOS subunits, 7 for complex I (MT-ND1, MT-ND2, MT-ND3, MT-ND4, MT-ND4L, MT-ND5, MT-ND6), 1 for complex III (MT-CYB), 3 for complex IV (MT-CO1, MT-CO2, MT-CO3) and 2 for complex V (MT-ATP6, MT-ATP8) (Anderson et al., 1981) (Figure 2).

Figure 2. Map of mitochondrial DNA (Taylor and Turnbull, 2005)

Genes are distributed asymmetrically between the two strands: H-strand encodes for most genes, both rRNAs, 14 tRNAs and 12 mRNAs of 13 subunits, but ND6 and 8 tRNAs are in L-strand (Attardi and Schatz, 1988). Furthermore, two non-coding regions (NCR) are present in the mtDNA. D-loop (Displacement Loop) is a triple-stranded region found in the major NCR of many mitochondrial genomes, and is formed by stable incorporation of a third, short DNA strand known as 7S DNA (Nicholls and Minczuk, 2014). D-loop is involved in many function, especially in mtDNA replication and translation, but also in mtDNA topology, mtDNA recombination, membrane association and dNTPs metabolism (Nicholls and Minczuk, 2014). The second NCR contains the origin of L-strand replication (O_L) and is located in a cluster of five tRNA genes (MT-TA, MT-TN, MT-TC, MT-TY) on L-strand, between nucleotides 5512 and 5903, around two thirds of the mtDNA length from the O_H (Anderson et al., 1981; Fernandez-Silva et al., 2003).

Similar to bacterial chromosomes, mitochondrial DNA is organized into tightly-packed nucleoprotein complexes called nucleoids. Nucleoids are found associated with the inner mitochondrial membrane, but can also freely diffuse through the mitochondrial network (Albring et al., 1977; Brown et al., 2011; Nicholls and Minczuk, 2014). The most thoroughly characterized nucleoid protein is the high-mobility group box protein TFAM (Parisi and Clayton, 1991).

The mtDNA replicates according to the strand-displacement model, with an asynchronous and asymmetric modality. DNA synthesis occurs continuously on both strands without Okazaki fragments (Clayton, 1991). There are two specific origins of DNA replication, one for each strand, the H-strand origin (O_H) and the L-strand origin (O_L). This is necessary to ensure correct DNA synthesis for both strands. Replication starts at O_H , and DNA synthesis proceeds in 5'-3' direction to produce a new H-strand. During the synthesis of the new H-strand, mtSSB covers the displaced, parental H-strand and blocks POLRMT transcription (Miralles Fusté et al., 2014). When the replication machinery exceeds O_L , it becomes single-stranded and folds into a stem-loop structure. The stem inhibits mtSSB binding and leaves the single-stranded loop region accessible for POLRMT, which initiates primer synthesis from a poly-T stretch (Fusté et al., 2010; Miralles Fusté et al., 2014). After about 25 nucleotides of primer synthesis, POLRMT is replaced by POLγ, and L-strand DNA synthesis begins. The replication of the two strands is interconnected because H-strand synthesis is required for the initiation of L-strand synthesis. Once initiated, H- and L-strand synthesis proceed continuously in opposite directions until the two events reach a full circle (Gustafsson et al., 2016).

Besides the replication origin of H-strand, D-loop contains a dedicated promoter for the transcription of each strand of mtDNA, the L-strand promoter (LSP) and the H-strand promoter (HSP). Transcription initiation at LSP or HSP produces near-genome-length polycistronic transcripts that encompass all of the coding information on each strand. The primary transcripts are processed to release the individual RNA molecules. The steady-state levels of the longer unprocessed transcripts are low and, therefore, processing is likely to occur co-transcriptionally. According to the "tRNA punctuation model" model, tRNAs are specifically recognized and cleaved in the polycistronic transcripts, thus leading to the release of tRNAs, mRNAs, and rRNAs (Anderson et al., 1981; Ojala et al., 1981), which subsequently undergo further maturation by, for example, base modifications, CCA addition, and polyadenylation (Hällberg and Larsson, 2014). In mammalian mitochondria, the 5' ends of tRNAs are cleaved in the polycistronic transcript by an all-protein version of ribonuclease (RNase) P, consisting of three subunits (MRPP1–3), whereas the 3' ends of tRNAs are processed by RNase Z (ELAC2) (Hällberg and Larsson, 2014).

Mitochondrial genetics

The mitochondrial genome differs from the nuclear one (nDNA) in many respects. First, the mtDNA genetic code uses only two stop codons: AGA and AGG (Temperley et al., 2010) (compared with UAA, UGA and UAG in nDNA), conversely UGA encodes tryptophan. To compensate for this UAA codons have to be introduced at the post-transcriptional level. In addition, AUA, isoleucine in nDNA, encodes for methionine in mtDNA (Chinnery and Hudson, 2013).

Second, mtDNA is maternally inherited. The prevailing theory of an “active elimination model” for paternal mtDNA suggests that sperm mitochondria are ubiquitinated and removed through different routes, such as proteosomal, lysosomal pathways or mitophagy (Carelli, 2015; Rojansky et al., 2016; Sato and Sato, 2013; Sutovsky et al., 1999). Moreover, autophagy has been recently highlighted as the mechanism for paternal mtDNA elimination in *Caenorhabditis elegans* (Al Rawi et al., 2011; Sato and Sato, 2011). Finally, a passive “dilution model” due to disproportionate amount of paternal *versus* maternal mtDNAs in mammals has been proposed. This was observed in mice (Luo et al., 2013), but not confirmed in humans (Pyle et al., 2015). Occurrence of paternal mtDNA transmission has also been documented in human (Schwartz and Vissing, 2002), and more often in animals (Dokianakis and Ladoukakis, 2014; Gyllensten et al., 1991; Zhao et al., 2004).

Finally, mtDNA variants may be present in homoplasmy or heteroplasmy, not in homozygosity or heterozygosity. Homoplasmy occurs when the sequence of multiple mtDNA copies are identical. However, heteroplasmy arises when a variant co-exists with its wild-type counterpart in various proportions, due to the polyploid nature of mtDNA (Chinnery and Hudson, 2013; Payne et al., 2013). A heteroplasmic variant can be inherit from mother to child and segregate in different tissue with varying loads, according to the ‘mitochondrial bottleneck theory’. During oogenesis and meiosis, cells incur to mtDNA reduction and amplification, leading to a purportedly random shift in mtDNA mutational load between cells (Chinnery and Hudson, 2013; Schon et al., 2012).

Mitochondrial haplogroups

The rate of evolution of the mitochondrial genome appears 10-fold higher than nuclear genome, mostly due to an elevated mutation rate of mtDNA (Brown et al., 1979). Due to the

high rate of evolution, mtDNA is an extremely useful molecule to exploit for high-resolution analysis in a wide range of fields, including evolutionary anthropology and population history, medical genetics, as well as forensic science (van Oven and Kayser, 2009). Thus, the mtDNA sequence evolved as a result of the sequential accumulation of mutations along maternally inherited lineages. All mtDNA types in the human gene pool can ultimately be traced back to a common matrilineal ancestor that lived approximately 200,000 years ago in Africa (Behar et al., 2008; Macaulay et al., 2005; Mishmar et al., 2003; van Oven and Kayser, 2009) and by migration colonized the world (Kivisild, 2015). Haplogroups are used to represent the major branch points on the mitochondrial phylogenetic tree and the migrations (Figure 3).

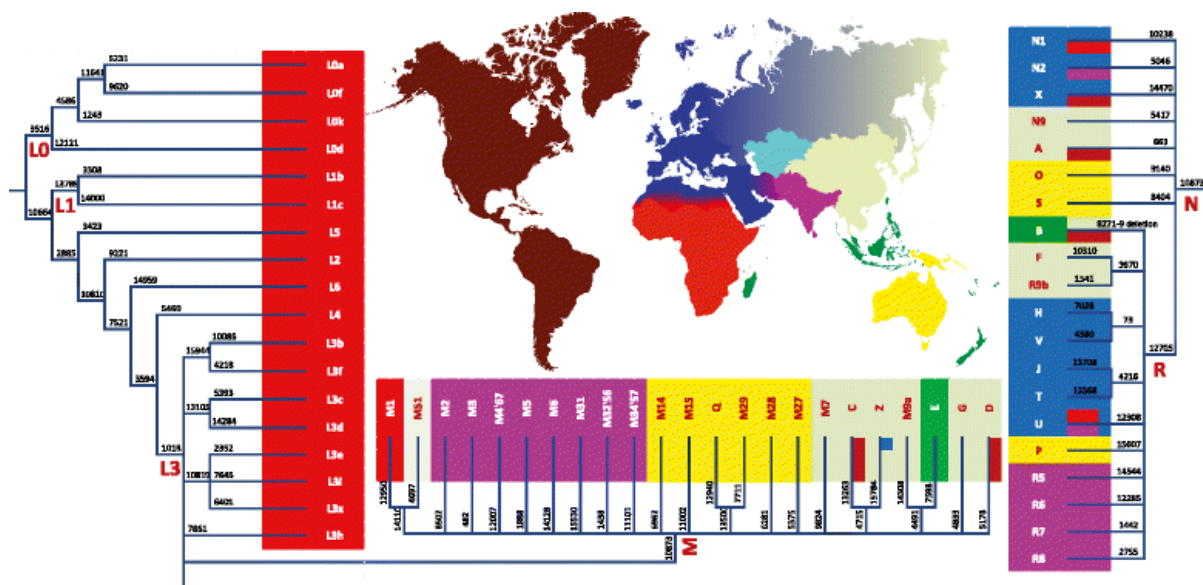

Figure 3 mtDNA haplogroup tree and distribution map (Kivisild, 2015).

The European population origins from the African haplogroup L3, followed by emergence of the major out-of-Africa haplogroups M and N (and N's descendants, R) in the vicinity of a putative "Gulf oasis" (Richards et al., 2016), subsequently followed by haplogroup R divergence (Pinhasi et al., 2012).

In the last decades, the possible role of mtDNA haplogroups in modulating mitochondrial function and pathology has been massively investigated. Interestingly, many studies have shown the associations of haplogroups with IQ (Skuder et al., 1995), sperm motility (Ruiz-Pesini et al., 2000), ability to adapt to climatic conditions (Ruiz-Pesini et al., 2004), body fat mass (Yang et al., 2011) and longevity (Cai et al., 2009; Santoro et al., 2006). Furthermore, this

association of mitochondrial haplogroups has been noticed in some pathologies, such as psychosis in bipolar disorder (Frye et al., 2017), motor function in long-term HIV-1 infected individuals (Azar et al., 2017), autism spectrum disorders (Chalkia et al., 2017), cardiomyopathy (Shin et al., 2000), multiple sclerosis (Kalman et al., 1999), Parkinson's disease (Ghezzi et al., 2005), Alzheimer's disease (Krüger et al., 2010; van der Walt et al., 2004), Friedreich's disease (Giacchetti et al., 2004), Amyotrophic Lateral Sclerosis (Mancuso et al., 2004) and Leber's Hereditary Optic Neuropathy (LHON) (Carelli et al., 2006; Hudson et al., 2007).

Leber's hereditary optic neuropathy (LHON)

LHON (OMIM #535000) is a blinding disorder, maternally inherited, characterized by acute or subacute loss of central vision, which affects predominantly young males, and is now recognized as the most frequent mitochondrial disease (Carelli et al., 2004, 2016; Yu-Wai-Man et al., 2011). The prevalence of LHON mutations in the population may vary from 1:10,000 in North East of England to 1:50,000 in Finland (Man et al., 2003; Puomila et al., 2007).

Clinically, LHON is characterized by painless, rapid loss of central vision in one eye, followed by a similar involvement of the other eye, usually in a short time laps, associated with dyschromatopsia (Carelli et al., 2004). In the acute phase, axonal loss in the papillo-macular bundle leads to temporal atrophy of the optic nerve, and the endpoint of the disease is generally a full optic atrophy with permanent severe loss of central vision, but with relative preservation of the peripheral visual field and pupillary light responses (Carelli et al., 2004). However, patients show occasionally a spontaneous recovery of visual acuity (Carelli et al., 2004; Mackey and Howell, 1992; Pezzi et al., 1998; Stone et al., 1992).

The peculiar feature of LHON is the selective degeneration of a single cell type, the retinal ganglion cells (RGCs). Thus, RGCs display somehow a unique sensibility to the mitochondrial energy defect generated by LHON pathogenic mutations. The 1.2 million axons that form the optic nerve originate from the RGCs in the inner retina (Carelli et al., 2004). These axons do not present a saltatory conduction of action potential until past the *lamina cribrosa*, due to absence of the myelin sheet, in order to maintain the optical transparency and consequently a good visual resolution (Howell et al., 2002). Thus, the high energy dependence of these cells

on mitochondrial OXPHOS may explain the particular sensitivity of RGCs and the related visual loss due to mitochondrial dysfunction (Carelli et al., 2004).

LHON is maternally inherited, due to the presence of point mutations on mtDNA. The most common pathogenic mutations are m.11778G>A/MT-ND4, m.3460G>A/MT-ND1, and m.14484T>C/MT-ND6, characterizing about 90% of LHON cases (Howell et al., 1991; Mackey and Howell, 1992; Wallace et al., 1988; Yu-Wai-Man et al., 2011). These “primary” pathogenic mutations are usually established as homoplasmic over multiple generations in LHON maternal lineages. However, two further features remain peculiar in LHON, i.e. the incomplete penetrance and the male prevalence (Caporali et al., 2017). Mitochondrial biogenesis, which is boosted in females by estrogens (Giordano et al., 2011), seems a major compensatory mechanism that determines incomplete penetrance (Giordano et al., 2014). On this, environmental factors, such as tobacco smoke (Sadun et al., 2004), and genetic modifiers, both in nDNA and mtDNA, are assumed to play a further role (Caporali et al., 2017).

Besides the 3 common “primary” LHON mutations, several other rarer pathogenic mutations have also been reported in single cases or families (Achilli et al., 2012). Moreover, additional recurrent polymorphic mtDNA variants were also associated with LHON and called “secondary” mutations (Brown et al., 1992; Johns and Berman, 1991; Johns and Neufeld, 1991). The role of these “secondary mutations”, widely debated (Mackey et al., 1996), was elucidated by firmly establishing these variants as mtDNA haplogroup-related polymorphic markers (Torrioni et al., 1996). Thus, multiple research groups confirmed the association of some LHON “primary” mutations with a specific mtDNA haplogroup, haplogroup J, as penetrance enhancer: in particular, this association is observed with the LHON m.11778G>A/MT-ND4 and m.14484T>C/MT-ND6 mutations (Brown et al., 1997; Lamminen et al., 1997; Torrioni et al., 1997). Over the years, this association was refined to specific clades of haplogroup J, the J1c and J2b clades characterized by accumulation of missense variants affecting both complex I and III (Carelli et al., 2006; Hudson et al., 2007). This association were validated in large cohorts of LHON patients of European descent, but a similar scenario seems to be confirmed also in LHON cohorts of Asian ancestry (Ji et al., 2008; Kaewsutthi et al., 2011). Furthermore, the complete sequence analysis of mtDNA carrying rare LHON mutation allowed to identifying private variants that may also act as genetic modifiers (Achilli et al., 2012). Multiple reports on Chinese LHON families indicated the occurrence of mtDNA backgrounds

characterized by an unusually high or even complete penetrance, frequently due to coexisting pathogenic mutations (Yang et al., 2009; Zhang et al., 2012). Opposite, in other maternal lineages it was observed an extremely reduced penetrance (Qu et al., 2009). Thus, different combinations including mtDNA haplotypes as defined by specific arrays of polymorphisms, private variants and co-existing mutations may all impinge on the pathogenic potential and, ultimately, on penetrance of LHON primary mutations. Remarkably, the role of the same mtDNA variant may vary drastically, for example, from adaptation at high altitudes, due to an environmental positive selection on the mtDNA sequence, to a pathogenic potential predisposing to LHON in different interacting environments (Caporali et al., 2017; Ji et al., 2008).

Interestingly, the pathogenic role of the m.14484T>C/*MT-ND6* mutation was initially not recognized because of the low phylogenetic conservation of the affected amino acid (Howell et al., 1991; Mackey and Howell, 1992). Remarkably, the m.14484T>C/*MT-ND6* change found on non-J mtDNA backgrounds displays a very low penetrance and has been occasionally reported in genetic surveys of control populations, thus behaving borderline and similarly to a polymorphic variant (A. Torroni, unpublished data) (Howell et al., 2003a; Palanichamy et al., 2004). Furthermore, different sets of two or more mtDNA variants have been postulated as modulators of penetrance, such as combinations of multiple private “weak” pathogenic mutations or combination of established LHON pathogenic mutations with variants, already known as markers of specific haplogroups, but detected outside the usual haplogroup background (La Morgia et al., 2008, 2014a).

A few studies tackled the issue of providing a functional evidence for the modifying role of the mtDNA haplotype and/or the private variants or co-existing mtDNA mutations. Initial studies based on MR-spectroscopy were unable to detect differences between LHON patients carrying the m.11778G>A/*MT-ND4* mutation associated or not with the mtDNA haplogroup J (Lodi et al., 2000). Exploiting the cell model of transmitochondrial cytoplasmic hybrids, “cybrids”, it has been shown *in vitro* that different mtDNA haplogroups may have slight, but significant differences in bioenergetic efficiency, production of ROS and stability of respiratory complexes assembly (Carelli et al., 2002; Gómez-Durán et al., 2010, 2012; Pello et al., 2008), thus substantiating their possible role as modifiers for LHON penetrance. Controversial results

were instead provided by the few studies on cases of LHON carrying double primary mutations (Brown et al., 2001; Caporali et al., 2017; Cruz-Bermúdez et al., 2016; Jiang et al., 2016).

Dominant optic atrophy (DOA)

Dominant optic atrophy (DOA, OMIM#165500), also known as Kjer's optic atrophy, is the most common amongst hereditary optic neuropathies, with an estimated disease prevalence varying from 1:10,000 to 1:30,000 (Lenaers et al., 2012). In year 2000, two independent groups identified pathogenic mutations in the OPA1 gene as causative for DOA (Alexander et al., 2000; Delettre et al., 2000). Nowadays, about 70% of DOA families have been linked to OPA1 mutations and more than 350 pathogenic mutations have been submitted to OPA1 databases, spread throughout the protein (Ferré et al., 2015; La Morgia et al., 2014b). The 50% of DOA patients carry stop-codon, frame-shift and deletion-insertion, leading to incomplete transcription and decreased protein content, with haploinsufficiency as the genetic mechanism. The remaining patients present missense mutations, which are thought to act through a dominant negative mechanism. In 2008, a particular group of missense mutations, affecting the GTPase domain, have been related to a syndromic form of DOA, associated with sensorineural deafness, ataxia, late-onset chronic progressive external ophthalmoplegia (CPEO) and mitochondrial myopathy with cytochrome c oxidase negative. This new phenotype was defined as DOA "plus" syndrome (Amati-Bonneau et al., 2008; Hudson et al., 2008; Yu-Wai-Man et al., 2010). Importantly, these patients harbored multiple deletions of mtDNA in their skeletal muscles, confirming the OPA1 function in mtDNA stability, as previously reported for its orthologue in *Saccharomyces cerevisiae* (Jones and Fangman, 1992; Guan et al., 1993). Thus, OPA1 has been added to the list of genes (ANT1, Twinkle, POLG, MFN2) associated with human disorders characterized by mtDNA deletions (CPEO syndromes) (DiMauro and Schon, 2008; Rouzier et al., 2012). Recently, other phenotypes have been reported within the frame of the DOA "plus" syndrome, including MS-like features (Yu-Wai-Man et al., 2016), Behr-like spastic paraparesis (Marelli et al., 2011), Parkinsonism and dementia (Carelli et al., 2015) and cases with absent or very mild ocular phenotype (Milone et al., 2009), thus expanding the spectrum of OPA1 spectrum.

As LHON, DOA is a hereditary neurodegenerative disorder, characterized by a tissue specificity, which is limited to RGCs and their axons forming the optic nerve, with a

preferential involvement of the small fibers belonging to the papillomacular bundle, which serve central vision. The main difference with LHON is slowly progressive course of bilateral visual loss, and as in LHON, DOA is usually symmetrical, associated with centrocaecal scotomas, impairment of color vision, temporal pallor of the optic disks and relative preservation of the pupillary reflex (Delettre et al., 2002; Lenaers et al., 2012; Yu-Wai-Man et al., 2010). The onset of DOA is usually during childhood, although the defect most frequently is diagnosed early in adult life. However, this optic atrophy shows wide variability in clinical expression between and within families, and visual impairment ranges from subclinical vision impairment to legal blindness (Barboni et al., 2014; Carelli et al., 2009; Yu-Wai-Man et al., 2010).

Postmortem histologic studies showed diffuse atrophy of the ganglion cell layer in the retina, with loss of myelin and axons within the optic nerves (Johnston et al., 1979), similar to the histopathology of LHON (Kjer et al., 1983). Analysis of the retinal nerve fiber layer (RNFL) thickness in DOA patients with optical coherence tomography (OCT), a non-invasive technique used to obtain high-resolution images, revealed generalized loss of fibers, typically prevalent on the temporal sector, with a smaller average optic disk size compared to a control population (Barboni et al., 2011, 2014; Milea et al., 2010).

Due to the variable clinical severity and incomplete penetrance observed in DOA, similar to LHON, the possible role of mtDNA haplogroups was investigated in DOA patients carrying OPA1 mutations. The two studies currently published reached contrasting conclusions on the possibility that the mtDNA background may act as modifying factor for DOA penetrance (Han et al., 2006; Pierron et al., 2009). Both studies examined a limited series of patients (29 and 41 respectively) and the study design did not take into consideration that DOA is a dominant disorder where the mtDNA haplogroup may be co-inherited with the OPA1 mutation from the mother or, alternatively, may change when the OPA1 mutation is inherited from the father. As a consequence, a study design just considering the simple association of the mtDNA haplogroup with OPA1 mutations does not take into account for these intricacies. Thus, only further studies of large cohorts of patients, with multiple segregations, may lead to a properly supported conclusion on the possible role played by mtDNA haplogroups in OPA1-related DOA (Caporali et al., 2017).

AIMS

The two most common inherited optic neuropathies due to mitochondrial dysfunction, Leber's Hereditary Optic Neuropathy (LHON) and Dominant Optic Atrophy (DOA), are both characterized by an incomplete penetrance and variable clinical severity, and in LHON there is also a clear-cut prevalence in males. These features remain poorly understood. LHON is genetically determined by missense point mutation in Complex I subunits genes encoded by the mitochondrial genome, whereas DOA is mostly due to heterozygous mutation in the OPA1 gene, encoding a mitochondrial fusion protein. In LHON, 90 % of patients carry one of three common primary mutations (m.11778G>A/MT-ND4, m.3460G>A/MT-ND1, and m.14484T>C/MT-ND6), the remaining 10% harbor a rarer mutation (Achilli et al., 2012). Since the identification of the first pathogenic mutation in mtDNA (Wallace et al., 1988), the role of the entire mitogenome has been investigated in many aspect of medicine, and particularly in LHON, suggesting a complex interaction between the pathogenic mutations, and the adaptive and private variants.

The first aim of this study is to determine the molecular basis of optic neuropathy in four families, negative for the common LHON pathogenic mutations, but still characterized by a clinical phenotype undistinguishable from LHON, which is maternally inherited at low penetrance. We will carry out the sequence of the entire mitochondrial genome in each of the four probands and perform confirmatory functional studies by assessing mitochondrial bioenergetics, taking advantage of the cybrids cell model to isolate the mitogenome contribution to the pathogenesis.

The second aim of this study is a large-scale analysis of the entire mitogenome in a large European cohort of LHON patients previously diagnosed as carrying the m.14484T>C/MT-ND6 mutation, the less frequent of the primary mutations. This analysis is specifically carried out to dissect the modifier role of the mitogenome genetic variation. The association of the three primary LHON mutation with specific mitochondrial backgrounds is largely known (Carelli et al., 2006; Hudson et al., 2007), and this is particularly stringent for the m.14484T>C/MT-ND6 mutation, but only a few families have been analyzed to date, and never at the resolution level of the entire sequence of the mitogenome.

Finally, the last aim is the analysis of the mitochondrial genome variability in DOA patients carrying OPA1 mutations. It is well established that DOA patients present a wide clinical variability between and within families, without a clear genotype-phenotype correlation with the OPA1 mutations. In previous studies, the association with the mitogenome genetic variation was tested, but the results of these study were unclear due to a faulty design (Han et al., 2006; Pierron et al., 2009). Thus, we re-consider the mitogenome genetic variation as possible modifier of patients' clinical outcome, measured as retinal nerve fibers layer (RNFL) thickness by OCT (optic coherence tomography). We will also investigate the possible relevance of coadaptation between the nuclear and mitochondrial genomes, by considering the mother-children segregations, where the mtDNA segregates with the OPA1 mutation, and father-children segregations, where the mtDNA does not segregate with the OPA1 mutation. For each mitogenome, we will define the mtDNA haplogroup, highlighting the private mutations, not belonging to the evolutionarily fixed changes, and predicting the effect by integration of conservation analysis and on-line prediction tools.

RESULTS

PART 1 - Peculiar combinations of individually non-pathogenic missense mitochondrial DNA variants cause low penetrance Leber's hereditary optic neuropathy

Pedigrees investigated

We observed three multigenerational pedigrees (Families 1a, b, and c in Figure 4) with multiple affected individuals fitting the clinical diagnosis of LHON and with a clear maternal transmission of the phenotype. Noticeably, all three pedigrees were from the same geographical area of southern Italy (Campania region).

Figure 4. Pedigree of Family 1 with the reconstructed genealogy (indicated by dashed lines) of its three branches (a, b, c). Affected individuals are indicated in black; probands are indicated by arrows.

A fourth smaller pedigree (Family 2; Figure 5) from northern Italy (Emilia-Romagna region) was observed with a single affected individual obeying the LHON clinical diagnosis. All four families tested negative for the three common LHON mutations at positions m.11778G>A/MT-ND4, m.3460G>A/MT-ND1 and m.14484T>C/MT-ND6.

Figure 5. Pedigree of Family 2. Affected individuals are indicated in black; proband is indicated by arrow.

Skeletal muscle investigations reveal normal activity of respiratory chain complexes but increased mitochondrial biogenesis

Histological analysis of skeletal muscle biopsies from the probands of Families 1a, 1b and 2 (Figures 4, 5) showed no overt signs of myopathy with minimal variability in fibers size, and histoenzymatic stain showed normal COX activity, but some increase of subsarcolemmal SDH reactivity (Figure 6A). Ultrastructure (TEM) analysis confirmed the presence of proliferated mitochondria under the sarcolemma and, occasionally, between fibers (Figure 6B). Mitochondrial DNA copy number and CS activity were both increased in skeletal muscles of patients as compared to controls (Figure 6C-D). Similarly, the specific oxidoreductase activities of Complex I, Complex II+III, Complex III and Complex IV were increased (Figure 6E), whereas when normalized on citrate synthase (CS) activity they were comparable to controls (Table 1). Taken together these data indicate the occurrence of an activated compensatory mitochondrial biogenesis, most likely due to a compensatory response caused by a mild mitochondrial defect, as previously reported (Giordano et al., 2014; Iommarini et al., 2012).

	CI	CII+III	CIII	CIV
Controls (mean \pm SD)	31.7 \pm 20.0	20.3 \pm 18.5	197.94 \pm 119.8	54.6 \pm 23.6
Family 1a IV:1	48.10	29.32	202.63	85.23
Family 2 IV:2	31.93	35.83	281.37	68.25

Table 1. Respiratory chain enzyme activity on skeletal muscle normalized for CS activity

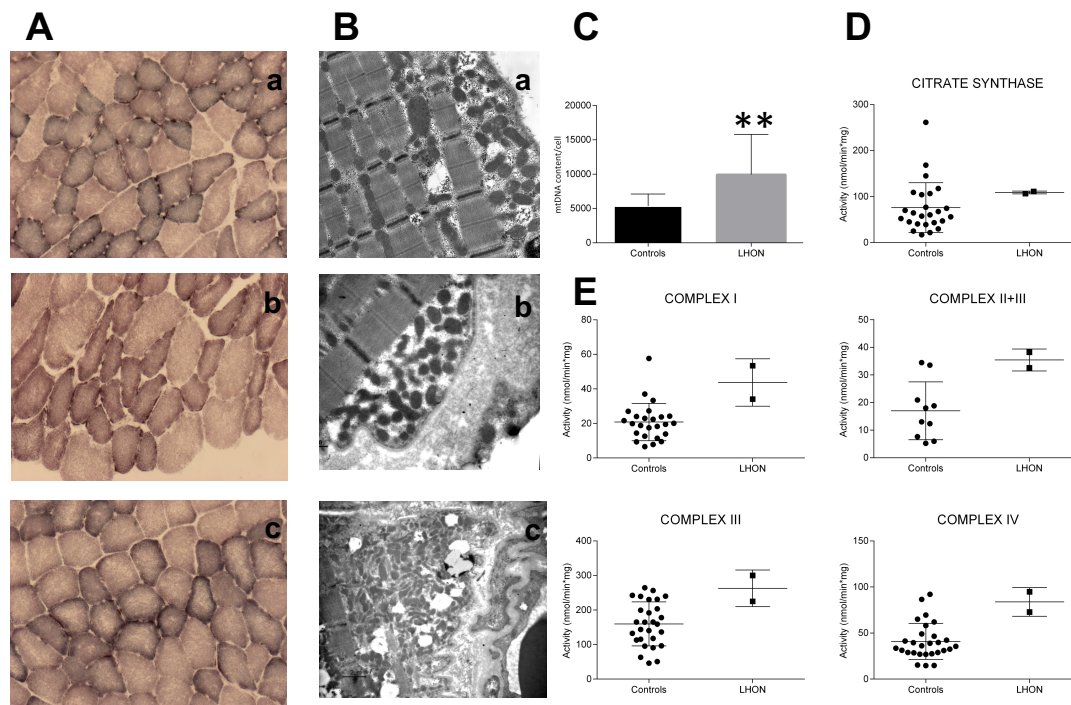

Figure 6. Morphological, molecular and biochemical analysis on skeletal muscle biopsies. A. SDH staining of skeletal muscle biopsies from individuals IV:1 from Family 1a (a), V:6 from Family 1b (b) and IV:2 from Family 2 (c). **B.** Transmission electron microscopy of the same muscle specimens as in A. Both SDH histoenzymatic staining (A) and ultrastructural evaluation (B) demonstrate mitochondrial proliferation as highlighted respectively by subsarcolemmal increase of SDH reaction and corresponding accumulation of mitochondria. **C.** Assessment of mtDNA content per cell, presented as column with mean \pm SD ($n=3$; $**p<0.001$), confirms the activation of mitochondrial biogenesis as shown by the significant increase in LHON samples. **D.** The evaluation of citrate synthase activity, presented as scatter plot with mean \pm SD, parallels again the results observed in C, with an increased mean value in the LHON samples. **E.** Evaluations of Complex I, Complex II+III, Complex III, Complex IV activities, presented as scatter plot with mean \pm SD, reveal an increase of all activities in LHON samples.

Molecular investigations, protein conservation, frequency, and phylogenetic analyses of the identified variants

Sequencing of the entire mitochondrial genome (mtDNA) from each of the probands independently ascertained for Families 1a, 1b and 1c revealed the same identical sequence, indicating that they descend from the same maternal ancestor, as also suggested by their geographical proximity. They all shared the diagnostic variants for haplogroup K1a and the following private mutations: non-coding m.2281A>G/MT-RNR2 and m.16129G>A/MT-HV1; synonymous m.6137T>C/MT-CO1, m.6329C>T/MT-CO1, m.8994G>A/MT-ATP6, m.11038A>G/MT-ND4 and m.15253A>G/MT-CYB; and missense m.14258G>A/MT-ND6 and m.14582A>G/MT-ND6. The m.14258G>A/MT-ND6 mutation causes the amino acid

substitution p.P139L, and the m.14582A>G/MT-ND6 the amino acid substitution p.V31A. Both missense mutations affect poorly conserved positions of the ND6 subunit of Complex I and are not predicted to be damaging (Figure 7, Table 2). However, the P139 position showed a higher conservation degree in mammals (37%) compared to eukaryotes (22%), being highest in primates (66%). Furthermore, the P139 position in mammals sits two amino acidic residues away from an invariant position (G141) and, in primates is contiguous to another invariant position (D138) within a moderately conserved domain (6 invariant positions out of 21) (Figure 7). The V31 position shows similar features. In eukaryotes and mammals, glycine is prevalent at position 31 with a low conservation (49% and 46%, respectively). In primates, at this position valine becomes prevalent with a higher conservation (77%). Most relevantly, V31 is within a highly conserved domain (10 invariant positions out of 21) in mammals, and is even more conserved in primates (16 invariant positions out of 21) (Figure 7).

Complete mtDNA sequence analysis of the proband from Family 2 showed all the variants diagnostic for haplogroup H5b and the following private mutations: synonymous m.10248T>C/MT-ND3; missense m.9966G>A/MT-CO3, m.10680G>A/MT-ND4L, m.12033A>G/MT-ND4 and m.14258G>A/MT-ND6. Besides the m.14258G>A/MT-ND6 nucleotide change, Family 2 also harbored the m.10680G>A/MT-ND4L and the m.12033A>G/MT-ND4 mutations that induce the amino acid changes p.A71T in ND4L and the p.N425S in ND4 subunits of Complex I, respectively. The p.A71T change affects a highly conserved ND4L position (86% in eukaryotes, 97% in mammals, invariant in primates), within an invariant stretch of 16 amino acids in primates (Figure 7, Table 2). Conversely, the p.N425S affects a highly conserved ND4 position only in primates (41% in eukaryotes, 70% in mammals, 87% in primates), in a moderately conserved domain (9 invariant positions out of 21) (Figure 7, Table 2). Both variants were considered neutral for the protein function by most of the prediction tools employed.

The m.14258G>A/MT-ND6 change, found in both Families 1 and 2, has been previously reported according to Mitomap and HmtDB in 10 different haplogroups, being diagnostic for haplogroups U3a1a1 and H1q3. Conversely, the m.14582A>G/MT-ND6 (Family 1) variant has been previously reported in seven different haplogroups, being diagnostic for haplogroup H4a. In these databases, the sample classified as GenBank: KC878720 is from our Family 1 and it was previously published (Costa et al., 2013) without considering the recurrence of a clinical

phenotype (A. Torroni, personal communication). The coexistence of m.14258G>A/MT-ND6 with the m.14582A>G/MT-ND6 variants is, however, unique to Family 1, when compared to all the other reported cases (Table 3).

Concerning the m.10680G>A/MT-ND4L variant, this has been found in 14 haplogroups and it has been previously reported as the only pathogenic change in three LHON families, arising as independent mutational events in haplogroups B4a1e, M13a1b and D6a1 (Zhang et al., 2012; Zou et al., 2010). In addition, this mutation has also been found in association with the m.14484T>C/MT-ND6 mutation in a further LHON family with a haplogroup B4d1 background (Yang et al., 2009). However, the m.10680G>A/MT-ND4L change has also been recognized in ten different maternal lineages with no pathology reported (Table 4).

Finally, the m.12033A>G/MT-ND4 variant has been reported in five different haplogroups in the general population, without being associated with any pathologic phenotype. Overall, the combination of the three coexisting missense changes m.10680G>A/MT-ND4L, m.12033A>G/MT-ND4 and m.14258G>A/MT-ND6 is a unique feature of Family 2.

Cybrid studies

To assess the pathogenic potential of the two peculiar combinations of missense variants found in Family 1 (m.14258G>A/MT-ND6 and m.14582A>G/MT-ND6) and Family 2 (m.10680G>A/MT-ND4L, m.12033A>G/MT-ND4 and m.14258G>A/MT-ND6) we generated cybrids using enucleated fibroblasts derived from the probands of Families 1a, 1b and 2, as cytoplasm donors. Different cell clones were obtained harboring each the two combinations of homoplasmic variants and used for subsequent investigations. In Figure 8, the data obtained from each LHON cell line were pooled together and compared to control cybrids, matched for haplogroup, having first verified that they had very similar functional profiles. To challenge the mitochondrial oxidative phosphorylation system, we grew cybrids in a glucose-free medium containing galactose; under these conditions, the rate of glycolysis is markedly reduced and cells are forced to rely on oxidative phosphorylation for ATP production (Robinson et al., 1992). No significant differences were found in LHON cell viability compared to controls (Figure 8A). Assessment of Complex I redox activity displayed a non-significant reduction in LHON cells (Figure 8B), indicating that the combinations of variants did not affect the overall Complex I function. However, the basal and the FCCP-stimulated oxygen consumption rate (OCR) of LHON cells were significantly reduced (Figure 8C). LHON cells also displayed a metabolic shift toward glycolysis, since they showed a higher ECAR and a lower OCR when compared to controls (Figure 8D). Consistently, the CS normalized ATP synthesis, driven by Complex I substrates (malate and glutamate), was significantly reduced in LHON cells, whereas ATP synthesis was normal when driven by Complex II substrates (succinate) (Figure 8E).

Although LHON mutations have been reported to exert their pathogenic role by increasing oxidative stress (Carelli et al., 2004; Yu-Wai-Man et al., 2011), we failed to reveal any difference between mutant and control cells in terms of superoxide anion and hydrogen peroxide production (Figure 9). Overall, these data indicate that combinations of polymorphic Complex I variants induce a mild bioenergetic defect.

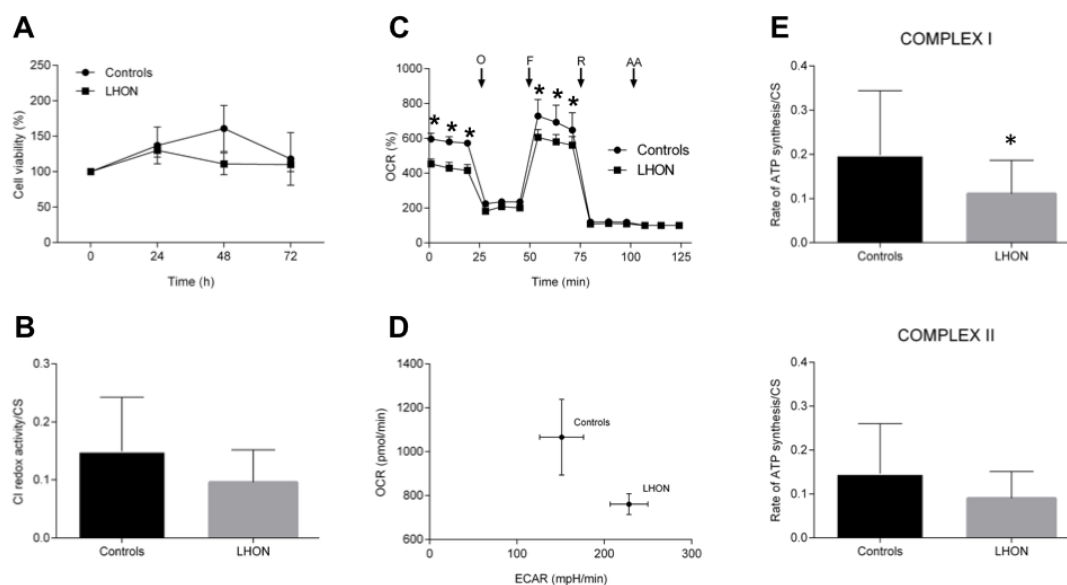

Figure 8. Biochemical characterization of cybrids clones. **A.** Cell viability after different time of incubation in galactose medium. Data are expressed as percentage of T0 ($n=12$; mean \pm SEM). **B.** Rotenone sensitive redox activity of respiratory complex I normalized for CS activity ($n=9$; mean \pm SD). **C.** OCR traces as pmol O_2 /min, after the injection of $1\mu M$ oligomycin (O), $0.2\mu M$ FCCP (F), $1\mu M$ rotenone (R) and $1\mu M$ antimycin A (AA) (mean \pm SD). Asterisks indicate statistical significance ($n=3$; * $p<0.05$). **D.** XFe Metabolic Phenogram. Basal OCR (pmol/min) and ECAR (mpH/min) rates were plotted in controls vs LHON cybrids, showing a metabolic shift in LHON cybrids towards glycolysis. **E.** ATP synthesis rates normalized for CS activity driven by complex I substrates (malate/glutamate) and complex II substrate succinate (mean \pm SD). Asterisks indicate statistical significance ($n=16$; * $p<0.05$).

Figure 9. Production of superoxide anion and hydrogen peroxide in hybrid cell lines. **A.** Mitochondrial superoxide anion production determined by epifluorescence microscopy using MitoSOX[™] fluorescent dye. Cells were visualized with a digital imaging system, using an inverted epifluorescence microscope (magnification x63/1.4 oil objective) at 580nm. Images are representative of 3 different experiments. **B.** Hydrogen peroxide levels were measured using H_2DCFDA by flow cytometry, as described in materials and methods. Data are mean \pm SD ($n=3$).

Modeling of the identified variants on the ovine Complex I structure

In order to define how such peculiar combinations of variants lead to a mild Complex I defect, we took advantage of the recently released structure of mammalian enzyme at 3.9 Å resolution, solved by cryo-electron microscopy (Fiedorczuk et al., 2016). We analyzed the position of amino acids affected by the polymorphic variants, namely m.14258G>A/MT-ND6, m.14582A>G/MT-ND6, m.10680G>A/MT-ND4L and m.12033A>G/MT-ND4 (Figure 10), but also the variants in three LHON Chinese families, with m.10680G>A/MT-ND4L found in combination with m.14484T>C/MT-ND6, m.3745G>A/MT-ND1, m.3548T>C/MT-ND1 m.3644T>C/MT-ND1, respectively (Yang et al., 2009; Zhang et al., 2012; Zou et al., 2010), and the adaptive variants (m.3745G>A/MT-ND1, m.4216T>C/MT-ND1, m.3394T>C/MT-ND1) for high altitude in Tibet (Ji et al., 2012; Kang et al., 2013) (Figure 11).

The variant m.14258A>G/MT-ND6 shared by Families 1 and 2 induces the P139L amino acid change in humans, which corresponds to A140 in ovine Complex I. Such amino acid is located in the transversal α -helix 5 of ND6. The variant m.14582A>G/MT-ND6 found in Family 1 generates the amino acid substitution p.V31A in humans and corresponds to G32 in the ovine complex, affecting the transmembrane α -helix 2 (TM2) of ND6. The m.10680G>A/MT-ND4L variant harbored by Family 2 affects the amino acid A71 of ND4L both in human and ovine Complex I. This amino acid lies in TM3 of the ND4L subunit. Lastly, the m.12033A>G/MT-ND4 induces the amino acid substitution p.N425S in the loop between TM13 and TM14 of ND4, which faces the mitochondrial matrix. Interestingly, with the only exception of the latter amino acid change, all the other variants affect positions around the putative E-channel of Complex I (Castellana et al., 2015), suggesting that the mild functional defect found in these patients may arise from an altered proton pumping caused by the two peculiar mtDNA combinations of variants (Figure 10).

Figure 10. Complex I model. Localization of polymorphic variants on the structure of the ovine complex I, (Fiedorczuk et al., 2016) using the UCSF Chimera software. The ovine amino acids Ala140 (corresponding to human p.P139L, m.14258G>A/MT-ND6), Gly32 (corresponding to human p.V31A, m.14582A>G/MT-ND6) and Ala71 (corresponding to human p.A71T, m.10680G>A/MT-ND4L) are shown as red-labelled spheres; whereas residues Glu143/ND1, Glu192/ND1, Glu34/ND4L, Tyr60/ND6, the key residues for the E-channel (near Q site), are shown as blue-labelled spheres. The structures of ND1, ND4L, ND6 and ND3 subunits are shown as ribbons, in green, blue, yellow and red, respectively. The combination of variants in Family 1 (A-B) and Family 2 (C-D) are displayed as front (A-C) and upper (B-D) views. Light blue arrows indicate the proposed proton translocation pathway (Fiedorczuk et al., 2016).

Figure 11. Combinations of mtDNA variants from three LHON Chinese families and single mtDNA variants, adaptive for high altitude in Tibet, on the ovine Complex I structure.

Positioning of the combinations of variants in three LHON Chinese families (**A-B**) (Yang et al., 2009; Zhang et al., 2012; Zou et al., 2010) and the adaptive variants for high altitude in Tibet (**C-D**) (Ji et al., 2012; Kang et al., 2013) on crystallographic structure of ovine Complex I (Fiedorczuk et al., 2016), using the UCSF Chimera software. In panels **A** and **B**, the ovine amino acids Ala71 (corresponding to human p.A71T, m.10680G>A/MT-ND4L) are shown as red labelled spheres, and this variant is associated in each families with Met65 (corresponding to human p.M64V, m.14484T>C /MT-ND6), Ala147 (corresponding to human p.A147T, m.3745G>A/MT-ND1), Leu81 (corresponding to human p.L81T, m.3548T>C/MT-ND1) or Val113 (corresponding to human p.V113A, m.3644T>C/MT-ND1), shown as green labelled spheres. In panels **C** and **D**, the ovine amino acids Ala147 (corresponding to p.A147T, m.3745G>A/MT-ND1), His304 (corresponding to human p.Y139H, m.4216T>C/MT-ND1) and Tyr30 (corresponding to human p.Y30H, m.3394T>C/MT-ND1) are shown as green labelled spheres. In all panels, residues Glu143/ND1, Glu192/ND1, Glu34/ND4L, Tyr60/ND6, the key residues for the E-channel (near Q-site), are shown as blue labelled spheres (Ji et al., 2012). The backbones of ND1, ND4L, ND6 and ND3 are shown as ribbons, in green, blue, yellow and red, respectively. The variants combination in LHON Chinese families (**A-B**) and adaptive variants for high altitude in Tibet (**C-D**) are displayed as front (**A-C**) and upper (**B-D**) views. Light blue arrows indicate the proposed proton translocation pathway.

PART 2 - Mitochondrial DNA variability in Leber's hereditary optic neuropathy**Mitochondrial genome sequencing and haplogroup affiliation**

We completely sequenced mtDNA in 147 probands, affected by LHON carrying the *m.14484T>C/MT-ND6* primary mutation, in apparently unrelated families from Europe (52 from Italy, 43 from Germany, 27 from France, 19 from UK, 3 from Spain and 3 from US, but with European ancestry).

Out of the entire cohort 28 probands were related and in table 5 the results of 119 unrelated mitochondrial genomes are shown: for each proband it is indicated the haplogroup affiliation, the private mutations not diagnostic for the haplogroup and the corresponding amino acid changes.

Table 5. Mitochondrial genome of LHON probands carrying m.14484T>C/MT-ND6 mutation with haplogroup affiliation (according to www.phylotree.org - build 17) and private changes. Missense variant in coloured according scoring criteria described in the “materials and methods” as in table 6.

In the LHON cohort of probands carrying the m.14484T>C/MT-ND6 mutation we found a statistically different frequency of mitochondrial haplogroups as compared to the European population (χ^2 test, $p < 0,0001$) (Figure 12). To understand which haplogroup generated this difference, all categories were compared to each other ($n=15$), indicating a major role for the haplogroup J and, less stringently, for haplogroup T (χ^2 test with Bonferroni correction), both over-represented and stemming from the same root. On the contrary, haplogroup H was consistently under-represented and to a lesser extent haplogroups K and U, these latter two sitting on the same root.

Figure 12. Frequency of European haplogroups in LHON cohort with m.14484T>C/MT-ND6 mutation and control population ($n = 10379$). ** $p < 0.001$, * $p < 0.05$.

Taking advantage of having the entire mtDNA genome sequence available, and in consideration of the strong association of haplogroup J with the m.14484T>C/MT-ND6 mutation, we dissected further haplogroup J into the sub-clades. Of relevance, previous studies reported the association with specific clades of haplogroup J, i.e. J1c (Carelli et al., 2006; Hudson et al., 2007). Our current results failed to highlight any significant difference amongst any of the haplogroup J sub-clades, in particular between J1 vs J2, or their sub-clades, as compared with

the European population (χ^2 test, J sub-clades $p=0.4046$, J1 sub-clades $p=0.1285$, J2 sub-clades $p=1.000$) (Figure 13).

Figure 13. Frequency of J1 and J2 clades, and their subclades in 55 LHON with m.14484T>C/MT-ND6 mutation on haplogroup J background and control population ($n=156$).

Evaluation of private missense variants

We analysed all missense changes, which were not diagnostic for the haplogroups, to detect other private variants, with some possible pathogenic significance. For each variant, the amino acid residue conservation and the *in-silico* prediction values of pathogenicity were considered (Table 6).

To this end, the *on-line* tools PolyPhen2, SIFT, PANTHER and PhD-SNP have been used and conservation analysis was carried out, as detailed in the methods. According to the scoring criteria described in the “materials and methods”, changes with a score of 0,66-1 points were considered pathogenic (red), with 0,5-0,65 points were considered synergistic (orange) and with 0-0,49 points neutral (black).

Nucleotide change	Gene	Amino-Acid change	Predictor tools				Conservation (%)			Invariants

Table 6. Prediction tools and conservation analysis of missense private variants in LHON probands carrying m.14484T>C/MT-ND6 mutation.

This analysis confirmed the pathogenic role of the m.14484T>C, found in all probands.

We detect the co-presence of 10 other possibly pathogenic mutations in 10 different pedigrees (Table 6). In 2 families, besides the primary LHON m.14484T>C mutation, a second LHON primary mutation was found (m.3460G>A and m.11778G>A). We also found 3 possibly

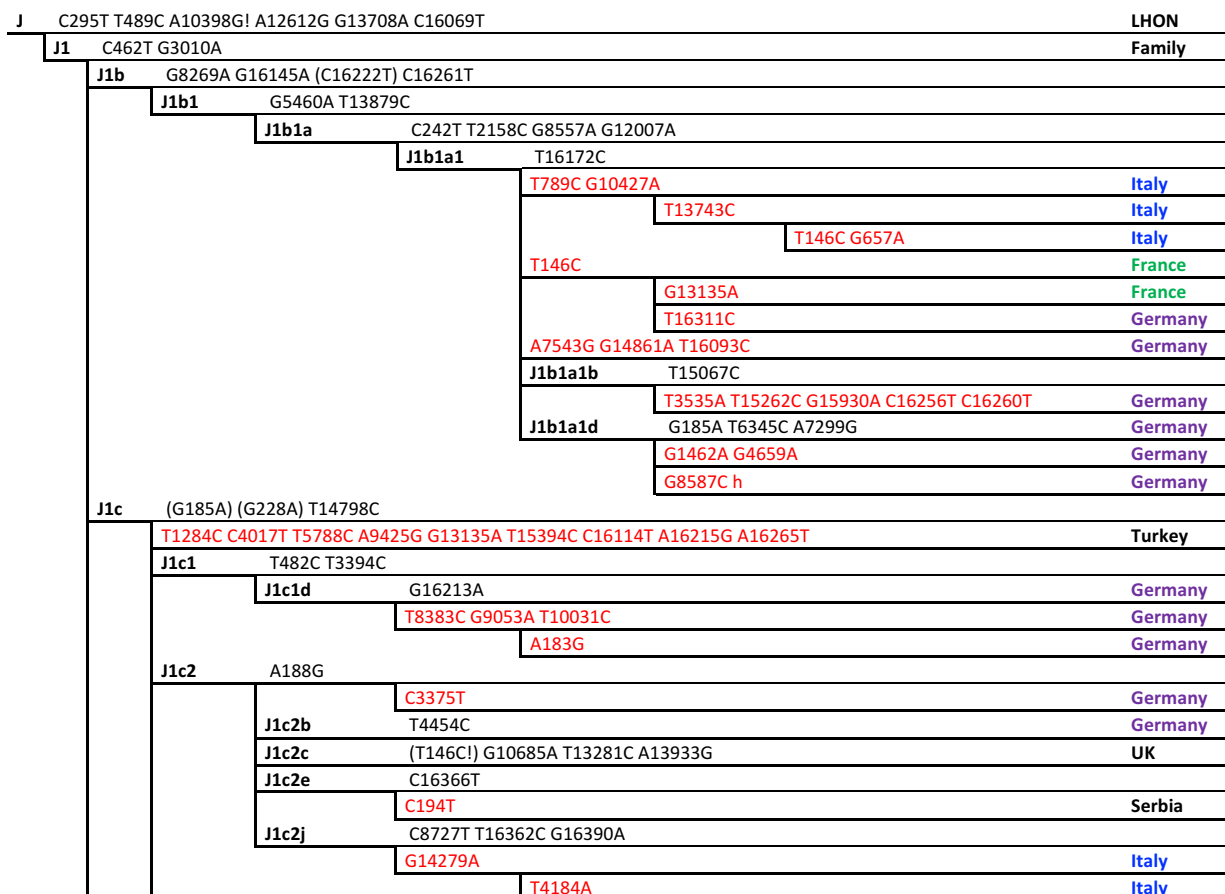

pathogenic mutations in MT-ND1 (m.4136A>G, m.4160T>C, m.4184T>A), 1 in MT-ND3 (m.10237T>C), 1 in MT-ND2 (m.4659G>A), 1 in MT-CO1 (m.6712A>T), 1 in MT-CO3 (m.9957T>C), 1 in MT-ATP8 (m.8516T>C) and 2 in MT-ATP6 (m.8989G>A, m.9025G>A).

Furthermore, 7 variants were predicted to be synergistic with the LHON m.14484T>C mutation: m.4824A>G in MT-ND2, m.6261G>A and m.7080T>C in MT-CO1, m.8557G>C in MT-ATP8, m.8812A>G (found in 2 families), m.8953A>G and m.9055G>A in MT-ATP6.

Phylogenetic analysis

To investigate any possible founder event, we reconstructed the phylogenetic tree starting from control population analysis in www.phylotree.org database (van Oven and Kayser, 2009). We show the branches of haplogroups J and T, because these two were the only with recurrent haplotypes (Figures 14).

A possibly ancient founder event is recognized on J1b1a1, which spread in central Europe with 3 families in Italy, 2 in France and 6 in Germany. Other founder events still occurring on haplogroup J are noticed on J1c1d, J1c2j, J1c3e2, J1c3f, J1c4 and J2b1 clades, but also on haplogroup T, in particular on T1a2, T2 and T2c1d1 clades (Figure 14).

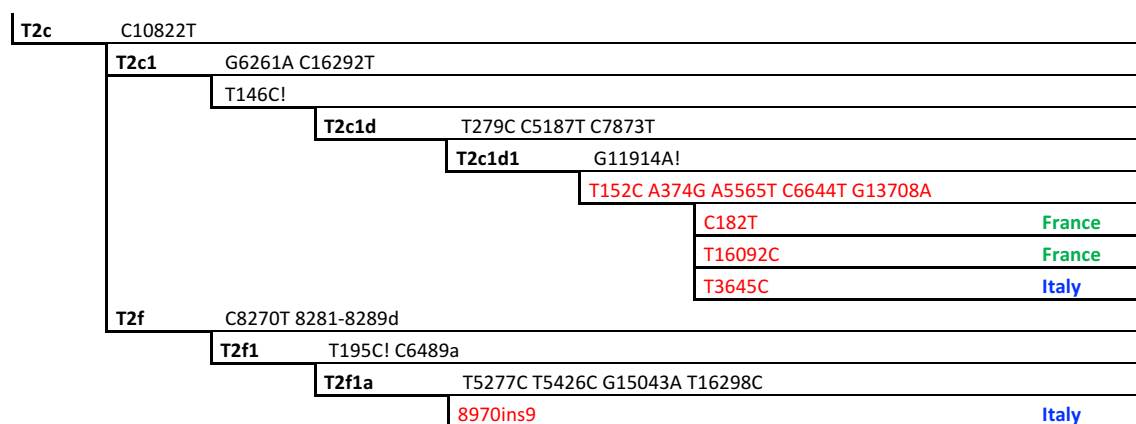

Figure 14. Phylogenetic reconstruction tree of LHON probands carrying m.14484T>C/MT-ND6 on haplogroups J and T, based on www.phylotree.org

Penetrance evaluation on available pedigree

To assess the role of haplogroup J on incomplete penetrance and male prevalence, we evaluated the number of affected versus unaffected carriers on the available reconstruction of the pedigrees (14 maternal lines on haplogroup J, 22 non-J). The results are summarized in tables 7 and 8.

	Males	
	Affected	Unaffected
J	27 (29.0)	66 (71.0)
non-J	42 (24.4)	130 (75.6)
All	69 (26.0)	196 (74.0)
	Females	
	Affected	Unaffected
J	10 (7.5)	123 (92.5)
non-J	10 (5.7)	166 (94.3)
All	20 (6.4)	289 (93.6)
	Total	
	Affected	Unaffected
J	37 (16.4)	189 (83.6)
non-J	52 (14.9)	296 (85.1)
All	89 (15.5)	485 (84.5)

Table 7. Frequency of affected and unaffected individuals within haplogroup J and non-J maternal lines, considering gender as variable. The data are expressed as n (%).

RATIO	Affected Male:Female	Affected:Unaffected	Male A:U	Female A:U
J	2,7	0,2	0,4	0,1
non-J	4,2	0,2	0,3	0,1
All	3,5	0,2	0,4	0,1

Table 8. Ratio of affected and unaffected individuals within haplogroup J and non-J maternal lines, considering gender as variable.

This analysis failed to highlight any significant difference. However, despite the lack of a strong evident effect, it remains a tendency towards higher penetrance of the m.14484T>C mutation on the haplogroup J background, which applies to both genders (Tables 7, 8).

PART III - Mitochondrial DNA variability in Dominant Optic Atrophy (DOA) with mutation in OPA1 gene

Mitochondrial genome sequencing and haplogroup affiliation

We completely sequenced the mtDNA in 112 maternally unrelated patients from 85 families carrying a dominant OPA1 mutation. The haplogroup affiliations and private variants are summarized in Table 9.

Table 9. Mitochondrial genome of DOA patients carrying OPA1 mutation with haplogroup affiliation (according to www.phylotree.org - build 17) and private changes. Missense variant in coloured according scoring criteria described in the “materials and methods” as in table 10.

In the OPA1 mutation cohort, as expected for a dominant disease, the frequency of mitochondrial haplogroups was not statistically different as compared to the Italian population (χ^2 test, $p = 5741$) (Figure 15).

Figure 15. Frequency of European haplogroups in DOA cohort with OPA1 mutations and control population ($n = 2495$). ** $p < 0.001$, * $p < 0.05$.

Private missense variants as phenotype modifiers

We analysed all missense changes, which were not diagnostic for the haplogroups, to detect other private variants, with some possible modifying or pathogenic significance. For each variant, the amino acid residue conservation and the *in-silico* prediction values of pathogenicity were considered (Table 10). To this end, the *on-line* tools PolyPhen2, SIFT, PANTHER and PhD-SNP have been used and conservation analysis was carried out, as detailed in the methods. According to the scoring criteria described in the “materials and methods”, changes with a score of 0,66-1 points were considered pathogenic (red), with 0,5-0,65 points were considered synergistic (orange) and with 0-0,49 points neutral (black).

Table 10. Prediction tools and conservation analysis of missense private variants in DOA patients carrying OPA1 mutation

In order to understand the influence of mitochondrial genome on the phenotype severity in patients with OPA1 gene mutation, we have analyzed the thickness of retinal nerve fiber layer (RNFL), measured by OCT (Optical Coherent Tomography), as marker of clinical outcome.

As a first step, we assessed the possible influence of private and putative pathogenic mutations (Table 10) disregarding the haplogroup affiliation on the RNFL thickness in OPA1 patients carrying or not carrying such variants. We failed to detect any differences in this comparison, considering the average RNFL thickness or sector by sector, i.e. temporal, superior, nasal, inferior (Figures 15, 16).

Figure 15. Scatter plot with mean \pm SD of average RNFL thickness in DOA patients with or without putative pathogenic mutations and synergistic variants in mtDNA.

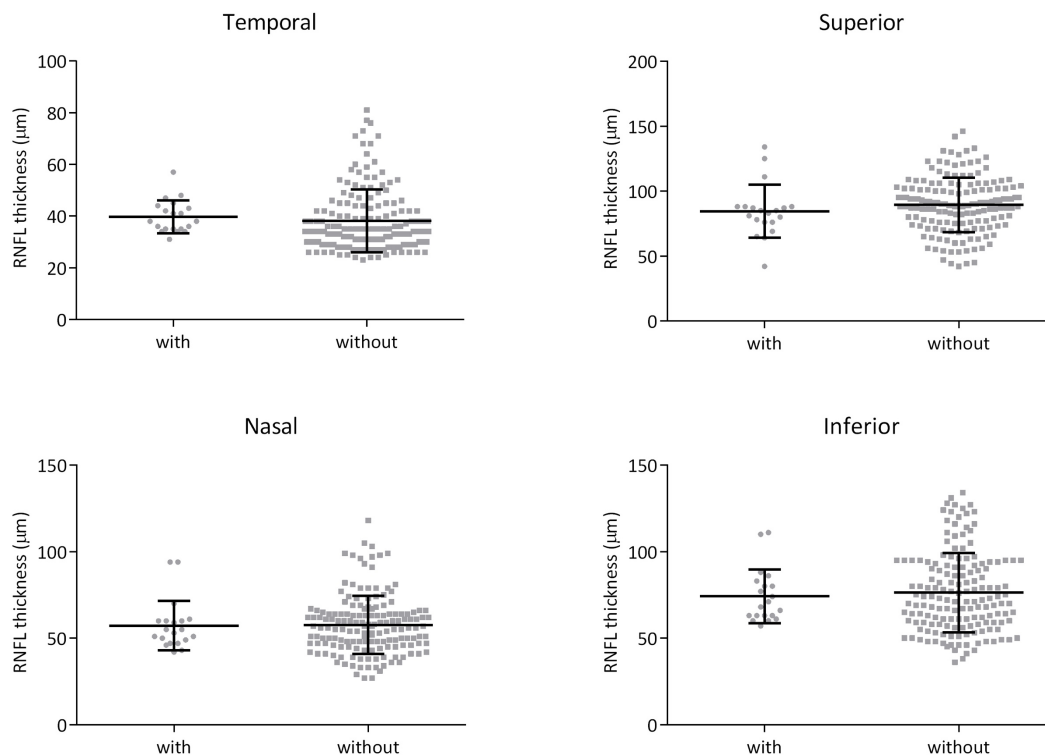

Figure 16. Scatter plot with mean \pm SD of RNFL thickness, split in four quadrants (Temporal, superior, nasal, inferior), in DOA patients with or without putative pathogenic mutations and synergistic variants in mtDNA

Mitochondrial haplogroups as phenotype modifier

Next, we investigated the variability of the RNFL thickness according to the different haplogroup affiliation of OPA1 patients, thus assessing the role of ancient mtDNA variation, selected and fixed during evolution as adaptive response to environmental pressure. The results are shown in Figures 17 and 18.

Figure 17. Scatter plot with mean \pm SD of average RNFL thickness in DOA patients with different mtDNA haplogroups.

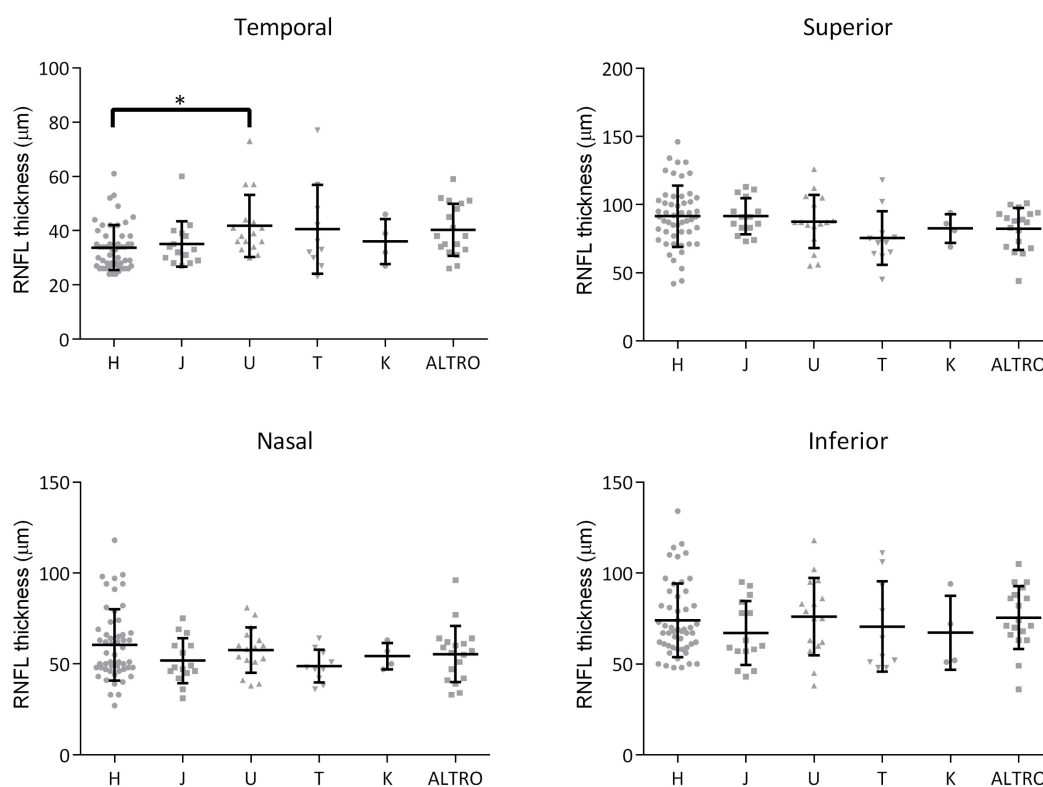

Figure 18. Scatter plot with mean \pm SD of RNFL thickness, split in four quadrants (Temporal, superior, nasal, inferior), in DOA patients with different mtDNA haplogroups. * $p < 0.01$

The only statistically significant difference emerges for the temporal RNFL thickness (ANOVA, $p=0.0270$), thus revealing a putative protective role for haplogroup U and damaging for haplogroup H (Uncorrected Fisher's LSD, $p=0.0053$) (Figure 18).

Finally, we investigated the interaction between the mitochondrial and nuclear genomes, assuming that there could be a coadaptation between the two genomes and changes may influence the clinical outcome. To analyze this interaction, we evaluated the severity of the disease as a function of OPA1 mutation co-segregating or not with the mtDNA genome. In short, given the different inheritance of the two traits, an individual always inherits mtDNA from the mother, while the OPA1 mutation can be inherited from each of the two parents. Based on this last criterion, we identified 35 parent-child segregations. These were then divided into two groups:

- 19 OPA1 segregations "without" mtDNA change (mother-children segregation);
- 15 OPA1 segregations "with" mtDNA change (father-children segregation).

We have thus analyzed the difference in RNFL thickness between the two generations of each segregation group to evaluate the severity of the clinical outcome. Interestingly, in the mother-children segregation group there was a significantly increased severity of fiber loss (lower RNFL thickness) in children for the average and inferior quadrant RNFL comparison, with a similar tendency for all other quadrants (paired t-test, $p=0.0186$, 0.0071 , respectively) (Figure 19). Noticeably, the infero-temporal fibers belong to the papillomacular bundle, which is the main target of the neurodegenerative process. Concerning the father-children segregation group, the only significant difference was found for the temporal quadrant (paired t-test, $p=0.0172$) (Figure 19).

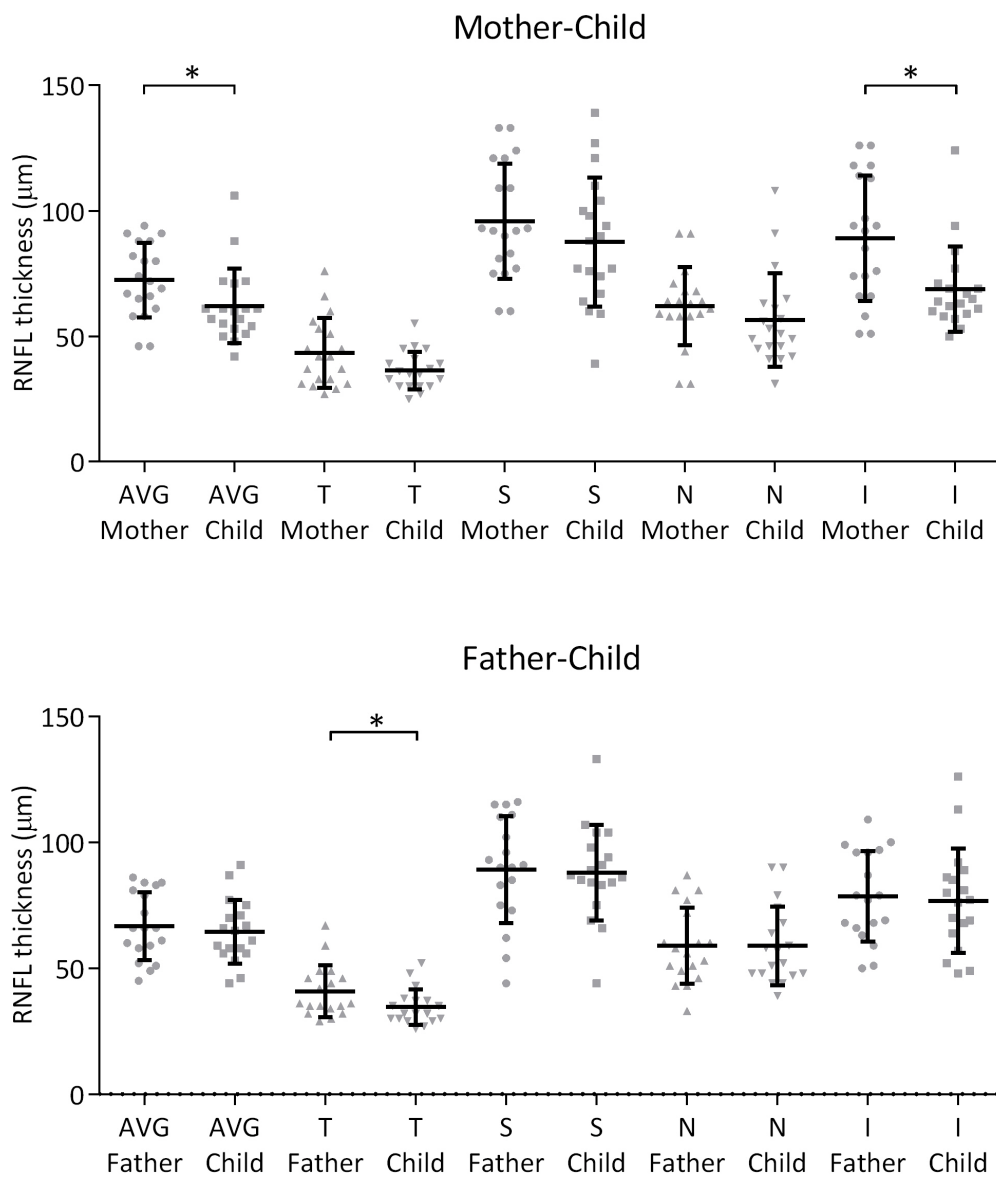

Figure 19. Scatter plot with mean \pm SD of differences in RNFL thickness from mother-children segregations and father-children segregations. * $p < 0.05$

DISCUSSION

Peculiar combinations of individually non-pathogenic missense mitochondrial DNA variants cause low penetrance Leber's hereditary optic neuropathy

LHON is now well established that is a disease determined by a very mild complex I-dependent respiratory chain dysfunction, somehow borderline between functional and pathological variability, which is certainly dependent on the presence of a major predisposing pathogenic mtDNA mutation ("primary" mutation), but also largely modulated by the mitogenome sequence variation (mtDNA haplogroup with "secondary" and private mutations) (Gómez-Durán et al., 2010, 2012). Furthermore, the respiratory defect and pathogenic mechanism seem also highly modulated by environmental (Ghelli et al., 2009) and nuclear DNA factors (Carelli et al., 2003). Thus, to date, by definition in a LHON family it has always been recognized a clearly pathogenic "primary" mutation, possibly modulated by other private or mildly deleterious variants, which were usually defined as "secondary" mutations (Caporali et al., 2017).

In this study, for the first time we provide a clear evidence that in the cluster of Families 1a, 1b and 1c, all belonging to the same maternal lineage and carrying the previously unreported combination of m.14258G>A/*MT-ND6* and m.14582A>G/*MT-ND6* variants on a K1a haplogroup background (Table 3), there was no clearly "primary" pathogenic mutation. Thus, the only variants we could assign a possible pathogenic role were the missense changes affecting the ND6 subunit of complex I, here found in a previously unreported combination, otherwise individually present in the known public datasets, but on different mitogenomes (www.mitomap.org). On the clinical ground, it is worth noting that all affected members ($n=14$) of this very large family are males, indicating that most likely the combination of missense variants on the K1 mitogenome characterizing Families 1a, 1b and 1c was not sufficient to cross the threshold for triggering LHON in females. Furthermore, general penetrance of these 14 affected members was 13% over the total number of individuals on the maternal line, and 25% over the total number of males. This latter percentage is well below the usual quote of average 50% penetrance in males reported in literature (Carelli et al., 2004; Yu-Wai-Man et al., 2011).

It is also interesting to note that the mitogenomes of both Families 1 and 2 had in common the m.14258G>A/*MT-ND6* change, a mutation previously not recognized as associated with LHON. The other variant m.10680G>A/*MT-ND4L* found in Family 2 has been either found alone in pedigrees segregating cases of LHON on the maternal line (Zhang et al., 2012; Zou et al., 2010), or in association with known LHON primary mutations (Yang et al., 2009). Moreover, the mtDNA sequence variants of these previously reported cases of Chinese ancestry are found in combination with other missense changes in Complex I subunits genes, in particular in the ND1 subunit (m.3644T>C/*MT-ND1*; m.3745G>A/*MT-ND1*; m.3548T>C/*MT-ND1*) or in the ND6 subunit (m.14484T>C/*MT-ND6*), which are closely assembled with ND4L according to the currently proposed Complex I crystal structure (Figure 11, Table 4) (Fiedorczuk et al., 2016). Thus, at least the m.14258G>A/*MT-ND6* (in the present study) and m.10680G>A/*MT-ND4L* variants have been recurrently associated with LHON, either in combination with other polymorphic variants or associated with other primary mutations. However, both variants alone are also reported in the normal population, remarking their non-pathogenicity when isolated (Tables 3, 4).

To validate on the functional ground the pathogenic role of the two combinations of variants found in Families 1 and 2, the only recognized method is to demonstrate a functional defect of mitochondrial respiratory chain in the cybrid cell model, where only the patient-derived mtDNA is transferred. We observed that ATP synthesis driven by Complex I substrates and respiration as measured by OCR were significantly defective in cybrids harboring the mitogenomes from Families 1 and 2 compared to haplogroup-matched controls. Remarkably, similar to the other LHON primary mutations with the exception of m.3460G>A/*MT-ND1*, the Complex I specific activity was not reduced in cybrids carrying the two combinations of variants (Carelli et al., 1997, 1999). Thus, even if other reports proposed that combinations of different variants might exert the equivalent pathogenic role of the single primary LHON mutation (Zhang et al., 2012; Zou et al., 2010), we here provide for the first time experimental evidence of the respiratory chain impairment from a functional point of view. Interestingly, the now available crystal structure of Complex I revealed that the large majority of these variants, either those found in the Italian Families 1 and 2, as well as those reported in Chinese families (Zhang et al., 2012; Zou et al., 2010) are located in close proximity to the predicted E-channel for proton translocation (Figures 10, 11), contributed by all three ND6, ND4L and ND1

subunits. Genetic variation along this pathway may alter the efficiency of proton translocation, ultimately affecting the energy conserving function of Complex I.

These results substantially change the general criteria used to date for the diagnosis of LHON, and, more in general, for the assessment of pathogenicity of mtDNA variants. In the case of the three branches of Family 1, we performed complete mtDNA sequencing because there was a clear evidence of maternal recurrence of a phenotype undistinguishable from classic LHON despite the absence of the three common LHON mutations. However, also the sequencing of the entire mitogenome in our entire cohort of Italian LHON families revealed the presence of multiple variants potentially relevant for LHON pathogenesis, beside the known primary LHON mutations. Therefore, we propose complete mitogenome sequencing as the gold standard for LHON diagnosis, to disclose possible unique combinations of variants, or double/triple mutants. In brief, the definition of a pathogenic mtDNA mutation becomes blurrier than ever, and only the accurate consideration of population-dependent mtDNA structure, combined with functional analyses using the cybrid cell model, may lead to its final validation. A good example for such a scenario is the m.3394T>C/*MT-ND1*, which might act as an adaptive variant selected for high altitudes in Tibet, while exerting a pathogenic effect on other mtDNA backgrounds and predisposing to LHON in China (Ji et al., 2012). Closely similar, other two adaptive variants for high altitude in Tibet, i.e. m.3745G>A/*MT-ND1* and m.4216T>C/*MT-ND1*, were also implicated in LHON (Kang et al., 2013). The m.3745G>A/*MT-ND1* was in fact found in combination with m.10680G>A/*MT-ND4L* in a Chinese LHON Family (Yang et al., 2009), whereas the m. 4216T>C/*MT-ND1* variant is at the shared root of the Western Eurasian haplogroups J and T, both possibly affecting the E-channel for proton pumping (Figure 11).

Mitochondrial DNA variability in Leber's hereditary optic neuropathy

The background mitogenome variability may be associated as a modifying factor to the "primary" mutations in LHON, this being particularly evident for the m.14484T>C/*MT-ND6* mutation. In fact, according to the current literature the mitochondrial haplogroup J is well established to be a modifier of penetrance for this mutation, with the strongest association compared with the other LHON primary mutations, whereas non-J mtDNA backgrounds

display a very reduced penetrance for the m.14484T>C/MT-ND6 mutation (Carelli et al., 2006; Howell et al., 2003a; Hudson et al., 2007; Palanichamy et al., 2004).

However, all previous studies on LHON cohorts did not analyze the entire sequence of mitogenomes, but only a few SNPs, which are diagnostic markers of haplogroups, or at best included in some studies the sequence of the control region, with only a few pedigrees analyzed, i.e. 6 and 33 respectively (Carelli et al., 2006; Hudson et al., 2007). Thus, we decided to collect all available LHON families carrying the m.14484T>C/MT-ND6 mutation in Europe and perform the complete sequence analysis of the mitogenomes, to dissect the genetic variability and its relevance for this specific LHON primary mutation. We collected, thanks to a relevant international effort and collaborations, and analyzed 147 probands from apparently unrelated families. Our results confirmed the strong association with haplogroup J. The 45% of this LHON cohort, carrying the m.14484T>C/MT-ND6 mutation, had a haplogroup J background as compared to the 9% in controls, further reproducing the results reported by previous studies (Carelli et al., 2006; Hudson et al., 2007; Torroni et al., 1997). However, in our hands the association was weaker than in previous reports: in the first report (Torroni et al., 1997) the patients analyzed were only two, both with J haplogroup, whereas a following study found a 66.7% (4 out of 6) of mutational events on J haplogroup (Carelli et al., 2006). Finally, the largest study ever by Hudson and colleagues reported a haplogroup J frequency of 99% in 851 LHON carrying m.14484T>C/MT-ND6 mutation, but this figure was reached by considering all individuals on the 33 available maternal lineages (Hudson et al., 2007).

Furthermore, the other difference we have observed between haplogroups T and H in our cohort may be due to the reduced frequency of haplogroup H, as counterpart of the J predominance, or to a milder modifier role of haplogroup T, which shares the common phylogenetic root as haplogroup J. This latter interpretation is corroborated by the normal distribution we have found by dissecting the haplogroup J sub-clades, compared to controls, failing to confirm the previously proposed preferential association of the J1 clade with the m.14484T>C/MT-ND6 mutation (Carelli et al., 2006; Hudson et al., 2007).

A side result of our sequencing analysis of such a large number of mitogenomes is the correction of previous haplogroup affiliation in some families, which was wrong. The previous analysis was carried out by RFLP, considering only a limited number of diagnostic variants for each haplogroup. In particular, the presence of the change m.10398A>G/MT-ND3 was

discriminating between haplogroup J and haplogroup T, while the change m.4216T>C/MT-ND1 was at the root of haplogroups J and T. From our new analysis, however, these changes were private variants, outside the canonical mtDNA background, confirming the complexity of the mitogenome variation.

The assessment of a possible functional impact of the missense private variants, besides the m.14484T>C/MT-ND6 mutation, was based on amino acid conservation and *on-line* prediction tools, and revealed in some instances double mutants and synergistic changes.

In 2 independent families, besides the primary LHON m.14484T>C/MT-ND6 mutation, a second LHON “primary” mutation was found (m.3460G>A/MT-ND1 and m.11778G>A/MT-ND4). This kind of event, though rare, was already reported in one family with both m.3460G>A and m.11778G>A and 6 families with both m.14484T>C and m.11778G>A (Brown et al., 2001; Catarino et al., 2017; Cruz-Bermúdez et al., 2016; Howell et al., 2002; Riordan-Eva et al., 1995; Tonska et al., 2008). Most cases carried the second “primary” mutation in a heteroplasmic state, besides one primary homoplasmic changes, and the coexistence of two primary mutations did not apparently modify the phenotype, most cases displaying a classic LHON (Catarino et al., 2017). Only in two families the double mutation seemed to increase the proportion of affected females, impacting on the male:female ratio (Catarino et al., 2017; Howell et al., 2002).

Other variants in CI subunits genes were predicted to be pathogenic: the m.4136A>G/MT-ND1, m.4160T>C/MT-ND1, m.4184T>A/MT-ND1, m.10237T>C/MT-ND3. The m.4160T>C/MT-ND1 (p.L285P) was already associated with LHON in an Australian family (Queensland family) carrying also the m.14484T>C/MT-ND6 and affected by a complex multisystemic neurological disorder compatible with the definition of LHON “plus” (Howell et al., 1991, 1995). The sequence analysis of this family was limited to the CI subunits genes only, and based on the reported data (Howell et al., 1991) the haplogroup affiliation of this Australian family is compatible with haplogroup U, carrying some diagnostic variants for this haplogroup (m.14647A>G/MT-ND6 and m.12372G>A/MT-ND6, both in MT-ND6). The family carrying the same combination of variants (m.4160T>C/MT-ND1 + m.14484T>C/MT-ND6) identified in our cohort is originally from France and showed the same haplogroup, U5a1a12b, suggesting a possible founder event or a migration of a female in Australia, even though the Queensland family was thought to be originally from Scotland. Furthermore, in a branch of the large

Australian pedigree there was a third m.4136A>G/MT-ND1 variant, which was proposed as an intragenic suppressor, ameliorating the complex neurological phenotype associated with complex I deficiency (Howell et al., 1991).

The m.4160T>C/MT-ND1 was also reported in patients with thymidine phosphorylase deficiency, as somatic mtDNA point mutation (Nishigaki et al., 2003) and in a healthy control (Lippold et al., 2014). Thus, the specific pathogenic role of this change affecting a conserved position remains uncertain.

The m.4136A>G/MT-ND1 (p.Y277C) variant was found in 49 controls, on 26 independent mtDNA backgrounds, but never on L2a1l2 (www.mitomap.org), as in our French proband, and it was also previously found associated to m.11778G>A/MT-ND4 LHON mutation in Italy, with a possible synergic role (La Morgia et al., 2008).

The m.4184T>A/MT-ND1 (p.F293Y) variant has never been found in the control population (www.mitomap.org); moreover, the same position, but with a different nucleotide change T>G causing a different amino acid substitution (p.F293C), was found mutated in a Russian LHON family carrying also the m.3460G>A/MT-ND1, on haplogroup T1 (Povalko et al., 2005).

The m.10237T>C/MT-ND3 (p.I60T) was found in 54 controls, on 20 independent mtDNA backgrounds, but never on the haplogroup T2b25 sub-clade (www.mitomap.org), as in our German proband. The same mutation was found in a Hungarian LHON patient not carrying the common primary mutations (Horvath et al., 2002).

The m.4659G>A/MT-ND2 (p.A64T) was found in 57 controls, on 27 independent mtDNA backgrounds, but never on the haplogroup J1b1a1d sub-clade (www.mitomap.org), as in our German proband. This variant was postulated to increase the risk of developing Parkinson disease (Khusnutdinova et al., 2008), and it also is a marker of haplogroup H2a1n.

Other putative “secondary” pathogenic mutations were found in CIV and CV subunits: m.6712A>T/MT-CO1, m.8516T>C/MT-ATP8, m.8989G>A/MT-ATP6, m.9025G>A/MT-ATP6 and m.9957T>C/MT-CO3. All these variants are rare, found a few times in the normal population (1, 4, 10, 24, 27, respectively), and never associated with pathologic phenotypes (www.mitomap.org). The only exception is the m.9957T>C/MT-CO3 variant, previously associated with several forms of mitochondrial encephalomyopathy: mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes (MELAS) (Manfredi et al., 1995), chronic progressive external ophthalmoplegia (CPEO) (Liu et al., 2011), and non-arteritic

ischemic optic neuropathy (Abu-Amero et al., 2005). A cell study on cybrids carrying this mutation showed a normal respiration, but increased ROS production (Lenaz et al., 2004).

The putative synergistic variants (m.4824A>G/MT-ND2, m.6261G>A/MT-CO1, m.7080T>C/MT-CO1, m.8557G>C/MT-ATP8, m.8812A>G/MT-ATP6, m.8953A>G/MT-ATP6, m.9055G>A/MT-ATP6) were found in 57, 1052, 253, 40, 18, 46, 4, 1769, 27 controls, respectively. All variants were not associated with any neurological conditions, except for the m.6261G>A/MT-CO1 and m.9055G>A/MT-ATP6 variants. The m.6261G>A/MT-CO1 variant, besides being found in cancer as a somatic mutation, was also associated with a LHON-like optic neuropathy in a patient negative for primary LHON mutations, on haplogroup T2 (Abu-Amero and Bosley, 2006). Moreover, this variant is a marker of several haplogroups (www.phylotree.org), which lowers its possible pathogenic role as a primary mutation. The m.9055G>A/MT-ATP6, in the frame of an association study of mitochondrial haplogroups and Parkinson disease, was assigned a putative protective effect for women (van der Walt et al., 2003). The same variant was studied in metabolic disease, failing to find any association (Saxena et al., 2006). After all considered, the m.9055G>A/MT-ATP6 is a marker of haplogroup K (www.phylotree.org), and was found on the haplogroup H in our case.

The phylogenetic analysis showed that some families cluster into a common origin, suggesting founder events. In particular, 11 probands, apparently independent from the geographical point of view, share the common J1b1a1 root, and diverged in at least 5 separate branches, which were country-related. There were similar events on J1c1d in Germany, on J1c2j, T1a2, T2 in Italy, on T2c1d1 in both Italy and France. All these cases may be the result of a founder effect, assuming that the m.14484T>C/MT-ND6 mutational event occurred early during the evolution and became fixed. Alternatively, the LHON mutational events might have arisen independently, suggesting that some mitogenomes could predispose to mutagenesis at position m.14484T. According to Carelli and colleagues (Carelli et al., 2006), the six Italian LHON families originally studied in their previous report carried the m.14484T>C/MT-ND6 mutation on independent mitochondrial backgrounds, thus the preferential association of the m.14484T>C/MT-ND6 LHON mutation with haplogroup J1 was interpreted as not due to founder events but to a true mtDNA background effect. It was also proposed that the specific combination of amino acid changes in the cytochrome b is the possible cause of the mtDNA background effect, and that this may occur affecting the supercomplex formation, by co-

assembling respiratory-chain complexes I and III (Carelli et al., 2006). However, differently from the Italian population, a clear major founder event that might have occurred 900–1,800 years ago has been recognized in Northern Europe (Dutch and French population) and in Canada (French-Canadian population) on haplogroup J1c1d (Howell et al., 2003b). The association of m.14484T>C/MT-ND6 mutation with haplogroup J does not apply to non-European population: for example, a study of an Indian LHON cohort showed an association with different mtDNA backgrounds (F1c1, M31a, U2a, M*, I1, M6, M3a1, and R30a), as independent mutational events (Khan et al., 2013).

Finally, on the clinical ground, penetrance in LHON families carrying the m.14484T>C/MT-ND6 mutation on haplogroup J was higher than those on non-J haplogroups. This was a non-significant tendency that applied to both genders. Unfortunately, besides the association studies there are no published data on this issue, with the actual calculation of penetrance in large cohorts of families, except for a few maternal lineages (Caporali et al., 2017). Moreover, as reported in literature, the ratio between affected males and females was 7.7:1 (Macmillan et al., 1998; Yu-Wai-Man and Chinnery, 2016). In our cohort, this ratio is about half (3.5:1), and in the haplogroup J background families it decreases to 2.7:1, while in the non-J was 4.2:1. Thus, the contribution of haplogroup J seems to be limited to a slight increase of penetrance, especially true in females carrying the m.14484T>C/MT-ND6 mutation.

Mitochondrial DNA variability in Dominant Optic Atrophy (DOA) with OPA1 mutations

Hypothetically, the mtDNA background may be also a modifier in DOA families carrying a mutation in the OPA1 gene, considering the consolidated role of mitogenome variability in LHON and the clinical and pathophysiological similarities between DOA and LHON. The mitochondrial haplogroups have been already investigated in DOA, and these studies failed to reveal any association (Han et al., 2006; Pierron et al., 2009). Our results confirmed this finding, as expected for a dominantly inherited disorder (Figure 15). We used the same mtDNA sequencing approach for DOA as for the m.14484T>C/MT-ND6 LHON cohort, and we have analyzed all private missense changes to detect the presence of putative pathogenic mutations or synergistic variants, besides the normal population-specific variability (Table 10). This analysis revealed 10 changes with a possible pathogenic role. Most of them are reported as rare population polymorphisms (www.mitomap.org). Both the m.4659G>A/MT-ND2

(p.A64T) and m.9957T>C/MT-CO3 variants were already found in our m.14484T>C/MT-ND6 LHON cohort, as well as associated to other neurological disorders. The m.4659G>A/MT-ND2 was postulated to increase the risk of developing Parkinson disease (Khusnutdinova et al., 2008), and is also a marker of haplogroup H2a1n. As commented in the previous paragraph, the m.9957T>C/MT-CO3 was found in 27 individuals, healthy controls and patients, and was previously associated with several form of mitochondrial encephalomyopathy (Abu-Amero et al., 2005; Liu et al., 2011; Manfredi et al., 1995) and its pathogenicity evaluated on cybrids (Lenaz et al., 2004). However, the pathogenic role of this mutation is now questioned based on our current results. Next, the m.15773 G>A/MT-CYB (p.V343M) was found in 39 controls, in 28 independent backgrounds, but never on H43 haplogroup, and, in particular, was found associated with the m.11778G>A/MT-ND4 LHON mutation, with a possible synergic role (La Morgia et al., 2008) supporting a putative role in modulating neurodegeneration.

Furthermore, the putative synergic variants m.4824 A>G/MT-ND2, m.7754 G>A/MT-CO2, m.7805 G>A/MT-CO2, m.8896 G>A/MT-ATP6, m.8953 A>G/MT-ATP6, m.12674 A>G/MT-ND5, m.14180 T>C/MT-ND6, found in the DOA cohort, were also found in 1052, 19, 334, 28, 4, 11, 138 controls respectively, and never associated with a pathological condition.

We thus investigated the mitogenome variability as a possible modifier in the DOA clinical outcome, evaluating the haplogroup association with the RNFL thickness, as evaluated by OCT and reliable readout of disease severity. First, we analyzed the effect of the putative pathogenic mutations and synergistic variant found in mtDNA. These mutations did not impinge on the clinical outcome of DOA patients (Figures 15, 16).

Second, we evaluated the mitogenomes variability, fixed by evolution (Figures 16, 17), finding that DOA patients on the haplogroup U background maintain a significantly higher RNFL thickness on the temporal quadrant as compared with those carrying haplogroup H. Remarkably, the specificity for the temporal fibers, which are the main disease target, possibly indicates a real protective role. Noticeably, haplogroup H is the most frequent in Europe and often found to be more prevalent in healthy control subjects than in patient study groups (Mueller et al., 2012), but sometime was also associated as risk factor, i.e. for late onset Alzheimer's disease (Santoro et al., 2010). Haplogroup U is the second most frequent, and haplogroup K stems from it as sub-clade. Haplogroup U has also been associated with several clinical conditions, i.e. psychosis in bipolar disorder (Frye et al., 2017), reduction of physical

performance (Arjmand et al., 2017), or severe progression of knee osteoarthritis (Rego-Pérez et al., 2008). However, this haplogroup as a whole, or in association with its sub-clade K, has also been assigned a protective role for Parkinson disease, a neurodegenerative disorder with a clear involvement of mitochondrial dysfunction, particularly of complex I, in its pathogenesis (Giannoccaro et al., 2017). This latter observation further supports that OPA1-related DOA, which has a documented complex I defect (Zanna et al., 2008), may benefit of a protective effect from the association with haplogroup U, in analogy with Parkinson disease.

Last, we evaluated the effect of the interaction between the mitochondrial and nuclear genomes. This approach is based on the widely discussed issue of preferential coadaptation between the nuclear and mitochondrial genomes, thus involving in the clinical outcome of DOA the co-inheritance of mtDNA changes with the OPA1 mutation (Figure 18). To this end, we compared the clinical severity, assessed as RNFL thickness in the two possible segregations mother-child (same mitogenome) vs father-child (change of the mitogenome haplogroup). This analysis revealed that the mother-children segregations displayed a statistically significant worsening of the clinical outcome, particularly on the average and inferior quadrant RNFL thickness, with the other quadrants (temporal, superior and nasal) presenting the same trend. On the contrary, the only significant difference in the father-children segregations was on the temporal quadrant, with a similar outcome on the other quadrants and on the average assessment. These results strongly indicate that the nuclear genome variation seems to play the major role on severity of DOA carrying dominant OPA1 mutations, as exemplified in the mother-child segregations where the mitogenome remains the same.

Common features between LHON and DOA

Interestingly, the otherwise normal variants found in the peculiar pathogenic combination in the two independent LHON families, were also found in both LHON and DOA cohorts. The m.14258G>A/MT-ND6 was found in one proband of the m.14484T>C/MT-ND6 LHON cohort, on a L2a1a1 mtDNA background, and in one patient with OPA1 mutation, on a K1a background. The m.10680G>A/MT-ND4L variant was found in 4 families on H, T2, U1a1a1 and X2d1 haplogroups, only in the LHON cohort. The m.14582A>G/MT-ND6 variant was found in 1 case on H1bm haplogroup, while the m.12033A>G/MT-ND4 was not found in any proband of the two LHON and DOA cohorts. These findings confirm the association of these variants

with LHON, especially the m.10680G>A/MT-ND4L, and their relative frequency in the population, although rare.

CONCLUSIONS

The current study provides genetic and functional evidence that specific and previously unreported combinations of missense mtDNA variants, which individually obey the definition of population polymorphisms, may exert a sufficient pathogenic potential for being causative of low-penetrance LHON.

This finding seems to be the extreme end of a wide and complex molecular landscape clearly implicating the interaction of the haplogroup-specific variants, as well as the private variants, with the clearly pathogenic mutations, as in the case of the LHON cohort carrying the m.14258G>A/MT-ND6 mutation. This interaction seems to be very strong also in the LHON cohort carrying the primary m.14484T>C/MT-ND6 mutation. The association with the haplogroup J root highlights this complex interplay, revealing also the importance of geographic mitogenome stratification with the occurrence of multiple founder events in Europe, as well as the possibility that certain mitogenomes may predispose to mutagenesis, which becomes eventually fixed during evolution.

More complex and still completely open is the scenario in DOA, where we documented a minor effect that could be ascribed to the mitogenome variation, as compared with what it seems a stronger role of nDNA modifying effect.

Overall, this study highlights the complexities of mtDNA sequence variability, introducing a perspective that will necessarily change the approach for assigning the pathogenic role to single or peculiar combinations of mtDNA variants, and modifying the criteria for diagnostics in mitochondrial human diseases (Montoya et al., 2009).

MATERIALS AND METHODS

Patients

Total DNA was extracted by standard methods from blood cells, urinary sediment epithelium and skeletal muscle after informed consent and approval of the internal review board at University of Bologna for Italian patients.

For the European LHON cohort carrying m.14484T>C/MT-ND6 mutation the informal consent was approved by local review board and total DNA was extract from blood.

The LHON cohort are composed by 147 probands: 52 from Italy (Prof. Carelli, University of Bologna, Institute of Neurological Sciences; Prof. Federico, University of Siena; Dr. Garavaglia and Dr. Zeviani, Besta Institute, Milan), 43 from Germany (Prof. Wissinger, University of Tubingen; Prof. Klopstok, University of Munich), 27 from France (Dr. Amati Bonneau, University of Angers), 19 from UK (Prof. Cinner, University of Chambridge), 3 from Spain (Prof. Montoya, University of Saragozza) and 3 from US (Prof. Sadun, Doheny Eye Centers-UCLA), but with European ancestry.

The dominant optic atrophy (DOA), carrying OPA1 mutations, are composed by 85 families with 112 maternally unrelated patients. The variants are described according to OPA1 transcript variant 1 (RefSeq: NM_015560.2) (Table 11). All patients were referred to Prof. Valerio Carelli, at Neurophthamology Clinic (IRCCS Institute of Neurological Science, University of Bologna).

Table 11. OPA1 mutation

The RNFL (retinal nerve fibers layer) thickness was evaluated in 91 patients, from 49 families, by the Stratus OCT (Optical Coherent Tomography), at Prof. Valerio Carelli's Neurophthalmology Clinic (IRCCS Institute of Neurological Science, University of Bologna) and Dr. Piero Barboni's clinic (Studio Oculistico d'Azeglio, Bologna). Data are shown in Table 12.

Sanger mtDNA sequencing

Direct sequence analysis of the entire mtDNA molecule was performed on total DNA, by Sanger (Torrioni et al., 2001). The protocol consists in 11 amplicons (Table 13). The PCR mixture contained 50 ng of DNA, 0.5U GoTaq® G2 Flexi DNA Polymerase 5U/μl (Promega), 1x Colorless GoTaq® Flexi Buffer 5X (Promega), 200 μM PCR nucleotides mix (Life Technologies), 200 μMeach primers (Sigma-Aldrich), in a final volume of 25 μl. The cycle conditions were 94°C for 5 min, 30 cycles of 30 sec at 94°C, 30 sec at 55°C, 72°C for 30 sec, and a final extension of 7 min at 72°C.

Table 13. 11 amplicons primer list for mitochondrial genome amplification

PCR product was displayed through electrophoretic run on agarose gel (1%), with the addition of GelStar (Lonza) at UV light, using as size marker GeneRuler 100 bp Plus DNA Ladder (Thermo Scientific). PCR products were purified with magnetic beads (AMPure XP, Beckman Coulter) following the manufacturer instructions.

The sequencing reaction mixture contained 100-200 ng of DNA template, 0.5% DMSO (dimethyl sulfoxide), 1.5µl of Sequencing Buffer 5X, 200µM of Primer, 1µl of BigDye Terminator 3.1 Cycle Sequencing Kit (Life Technologies), in a final volume of 10µl

The cycle conditions were 25 cycles of 10 sec at 96°C, 5 sec at 50°C, 4 min at 60°C. For each amplicon three primers were used to sequence and their details are shown in Table 14.

Table 14. Primer list for mitochondrial genome sequencing

Sequence analysis was performed using the Sequencer 4.10 software (Gene Codes), comparing with the reference mitochondrial DNA sequence, rRCS (NC_012920) (Andrews et al., 1999).

NGS mtDNA sequencing

The Next Generation Sequencing (NGS) protocol consists in two long PCR amplicons (9.1 kb and 11.2 kb) (Stawski, 2013) and we amplified using Q5 High-Fidelity DNA Polymerase (with fidelity 280 times higher than Taq) (New England Biolabs). The PCR mixture contained 50 ng of DNA, 1U Q5 High-Fidelity DNA Polymerase (New England Biolabs), 1x Q5 Reaction Buffer (New England Biolabs), 200 μ M PCR nucleotides mix (Life Technologies), 500 μ M each primer (Sigma-Aldrich), in a final volume of 25 μ l. The cycle conditions were 94°C for 5 min, 30 cycles of 30 sec at 94°C, 30 sec at 55°C, 72°C for 30 sec, and a final extension of 7 min at 72°C (Table 15).

Primer	Position (mtDNA)		Sequence (5'-3')	Length product (bp)

Table 15. NGS primer list for mitochondrial genome amplification

PCR product was displayed through electrophoretic run on agarose gel (1%), with the addition of GelStar (Lonza) at UV light, using as size marker EZ Load™ 1 kb Molecular Ruler (Bio-Rad).

PCR products were purified with magnetic beads (AMPure XP, Beckman Coulter) following the manufacturer instructions.

The library was constructed by Nextera XT DNA Library Preparation Kit (Illumina, San Diego, CA). After fluorimetric quantification, using Quantus Fluorometer with Quantifluor dsDNA System (Pomega), the target DNA were diluted to the final concentration of 0,4 ng μ L. The first step is tagmentation reaction, using "NexteraXT Transposome", which fragment DNA adding simultaneously DNA adapters ends. The reaction, in a final volume of 20 μ l, contains 2 ng of DNA, 10 μ l TD (Tagment DNA Buffer), 5 μ l of ATM (Amplicon Tagment Mix), incubated at 55°C for 5 min, and immediately added 5 μ l of NT (Neutralize Tagment Buffer) and incubated at 25°C for 5 min.

Then, a PCR amplification (Limited-Cycle PCR) added the Index 1 (i7), Index 2 (i5), and full adapter sequences to the tagmented DNA from the previous step. Every sample had a unique index combination, to be distinguished in the sequences reaction. 15 μ L of NPM (Nextera PCR Master Mix), 5 μ L of index 1 primers (N7XX) and 5 μ L of index primers 2 (S5XX) are added. Thermalcycler program is 72°C for 3 min, 95°C for 30 sec, 12 cycles at 95°C for 10 sec, 55°C for 30 sec, 72°C for 30 sec, final extention at 72°C for 5 min and hold at 10°C.

The PCR product were purified using magnetic beads, AMPure XP (Beckman-Coulter), following the manufacturer instructions, and quantified with fluorimetric method Quantus Fluorometer with Quantifluor dsDNA System (Promega). The normalized DNA were pooled. The pool where quantified and concentration is converted from ng/ μ L to nM, according with this formula:

$$(concentration\ in\ ng/\mu l) / (660\ g/mol \times average\ library\ size) \times 10^6 = concentration\ in\ nM$$

where 660g/mol represents the mean value of the molar mass of a pair of dsDNA bases, assuming that average size of the bases is 650 bp. Pool were diluted to a final concentration of 4 nM.

5 μ L of the 4nM library are added to 5 μ L of fresh NaOH 0,2 N, mixed and incubated at room temperature for 5 min for DNA denaturation. A volume of 990 μ L of cold Hybridization Buffer are added to obtain a library final concentration of 20 pM. Simultaneously, the PhiX control library, mixing mtDNA library with 1% of PhiX in 600 μ L final volume, was carried out on the

MiSeq (Illumina) sequencer.

The sequencing parameters consisted in 150 cycles in Paired End (2x150) on MiSeq Reagent Kit v3, 600 cycles (Illumina).

Sequence output given from sequencer is a file in FASTAQ format, where each base call is associated to a “quality score”. Through instrument software (MiSeq Reporter), sequences are aligned to the mitochondrial genome reference sequence, rCRS (revised Cambridge Reference Sequence), creating the alignment file (BAM) and identifying also sequences variants (variant calling), listing in a VCF file (Variant Call File).

Population frequencies of missense mutations and the mtDNA backgrounds on which they were observed were recovered from two public databases, Mitomap (<http://www.mitomap.org>) and HmtDB (<http://www.hmtdb.uniba.it>) (Lott et al., 2013; Rubino et al., 2012). Haplogroup affiliations of mitogenomes were assigned according to PhyloTree (www.phyloree.org) (van Oven and Kayser, 2009).

Protein conservation analysis and homology modelling

Protein conservation analysis and pathogenicity prediction were carried out considering *in silico* protocol (Polyphen2, SIFT, FatHm, PROVEAN, MutationAssessor, CADD, PANTHER, PhD-SNP, MtoolBox, APOGEE_boost) (Achilli et al., 2012), available on MitImpact 2.7 databases (mitimpact.css-mendel.it) (Castellana et al., 2015), and conservation analysis on mammals, evaluating the amino acid residue conservation (> 70%), local conservation value > global storage value, invariant residue included in “-4/+4” range. An average score (0-1) for each missense variant has been calculated and changes with a score of 0,66-1 points were considered pathogenic, with a score of 0,5-0,65 points were considered synergistic and with 0-0,49 points neutral.

Positioning of amino acid changes on the 3D structure of respiratory Complex I was performed using UCSF Chimera 1.11.2 (www.cgl.ucsf.edu/chimera/) using as a template the molecular model of ovine respiratory Complex I (PDB file 5LNK) (Fiedorczuk et al., 2016).

mtDNA copy number quantification

Absolute quantification of mtDNA relative to nuclear DNA (nDNA) was performed by a real-time PCR based method using the LightCycler480 (Roche). This method is a multiplex assay

based on hydrolysis probe chemistry. A mtDNA fragment (ND2 gene) and a nDNA fragment (FasL gene) were co-amplified by multiplex polymerase chain reaction according to the primers, probes and conditions previously published (Cossarizza et al., 2003). These two fragments were cloned tale to tale in a vector and serial dilutions were used to construct a standard curve, obtaining a ratio of 1:1 of the reference molecules. Primers and probes sequences and PCR conditions are available on request.

Skeletal muscle investigation

Tibialis anterior muscle biopsy was carried out and routine histological and histoenzymatic analysis, including cytochrome c oxidase (COX) and succinic dehydrogenase (SDH) activity staining, were performed (Dubowitz et al., 2013). Respiratory chain complexes and citrate synthase (CS) redox enzymatic activities were determined on skeletal muscle homogenates as previously reported with minor modifications (Caporali et al., 2013; Trounce et al., 1996). Measurements were performed at 37°C by using a dual-wavelength spectrophotometer (V550 Jasco Europe, Italy), under constant stirring of the samples diluted in the assay buffer (50 mM KH₂PO₄ (pH 7.6), 1 mM EDTA, 2.5 mg/ml BSA). For Complex I NADH:DB:DCIP oxidoreductase activity was assessed in the presence of 60 μM DCIP (λ_{\max} : 600 nm; ϵ_{DCIP} : mM⁻¹ cm⁻¹), 70 μM DB, 0.3 mM KCN and 200 μM NADH (Janssen et al., 2007), after the subtraction of 1 μM rotenone-insensitive activity. The antimycin A-sensitive ubiquinol:cytochrome c reductase activity of Complex III was determined in the presence of 50 μM decylbenzoquinol (DBH₂), 0.3 mM KCN and 20 μM bovine heart cytochrome c (λ_{\max} : 550–540 nm; ϵ_{cytc} = 19.1 mM⁻¹ cm⁻¹). The Complex II+ III activity was measured as the succinate:cytochrome c reductase activity in the presence of 5 mM succinate, 0.3 mM KCN and 20 μM bovine heart cytochrome c, after the subtraction of 5 mM malonate- and 1 μM antimycin A-insensitive activity. The Complex IV activity was determined adding 60 μM of reduced bovine heart cytochrome c, after subtraction of 0.3 mM KCN-insensitive activity. Data were corrected for citrate synthase activity (Trounce et al., 1996) and protein content measured with Bradford assay. Skeletal muscle biopsies also underwent transmission electron microscopy (TEM) analyses using standard procedures.

Generation and maintenance of cybrids

Cybrid cell lines were generated in Dr. Monica Montopoli's Laboratory (Department of Pharmaceutical and Pharmacological Sciences, University of Padova) from patient's skin fibroblasts and 143B.Tk⁻ cells, as previously described (King and Attardi, 1996). Cybrids were grown in Dulbecco's modified Eagle medium (DMEM) supplemented with 10% fetal calf serum (South America source from Gibco, Life Technologies), 2 mM L-glutamine, 100 U/ml penicillin, 100 µg/ml streptomycin, in an incubator with a humidified atmosphere of 5% CO₂ at 37 °C.

Cell viability assessment

For viability experiments, cells (4×10^4 cells/cm²) were seeded in 24 well plates and incubated for different times in glucose-free DMEM supplemented with 5 mmol/L galactose, 5 mmol/L Na-pyruvate and 5% FBS (DMEM-galactose). Viability was determined using the colorimetric sulforhodamine B (SRB) assay (Scarlati et al., 2003). Briefly, at the end of incubation time, cells were fixed with 50% trichloroacetic acid (TCA) for 1 hour at 4°C, washed 5 times with H₂O and dried for 1 hour at room temperature. Cells were then stained with SRB 0.4% diluted in 1% acetic acid for 1 hour at room temperature, washed 4 times with 1% acetic acid. SRB was solubilized with 10 mM Tris-HCl pH 9.8. The absorbance of SRB was detected by measuring the SRB absorbance at 570 nm with a VICTOR³ Multilabel Plate Counter (PerkinElmer Life).

Oxygen consumption rate

Oxygen consumption rate (OCR) and extracellular acidification rate (ECAR) were measured in adherent cells with an XFe²⁴ Extracellular Flux Analyzer (Seahorse Bioscience, Billerica, MA, USA), as previously described (Iommarini et al., 2014). OCR and ECAR were measured under basal conditions and after the sequential addition of 1 µM oligomycin, 0.2 µM FCCP (carbonylcyanide-p-trifluoromethoxyphenyl hydrazone, Sigma-Aldrich, Milan, Italy), 1 µM rotenone and 1 µM antimycin A. Data were normalized on SRB-based cell quantification and expressed either as rate (pmol O₂/min or mpH/min) or as percentage of OCR compared to non-mitochondrial residual OCR.

ATP synthesis

The rate of mitochondrial ATP synthesis was measured in digitonin-permeabilized cybrids using the previously described luciferin/luciferase assay, with minor modifications (Giorgio et al., 2012). Briefly, after trypsinization, cells were resuspended (10×10^6 /mL) in buffer A (10 mM KCl, 25 mM Tris-HCl, 2 mM EDTA, 0.1% bovine serum albumin, 10 mM potassium phosphate, 0.1 mM $MgCl_2$ (pH 7.4)), kept for 15 minutes at room temperature, and then incubated with 50 μ g/mL digitonin for 1 minute. After centrifugation, the cells pellet was resuspended in buffer A and aliquots were taken to measure ATP synthesis, protein content, and CS activity. Aliquots of cells were incubated with 5 mM malate plus 5 mM pyruvate (complex I-driven substrates) in the presence or absence of 10 μ g/mL oligomycin, or with 10 mM succinate plus 2 μ g/mL rotenone (Complex II-driven substrate), and 0.2 mM ADP for 1 and 3 minutes. The amount of ATP was measured as described (Zanna et al., 2005). Adenosine 5'-triphosphate (ATP) Bioluminescent Assay Kit was from Sigma Aldrich. Data were normalized on protein content measured by Bradford assay and the rate of ATP synthesis was expressed as a ratio on CS activity (Trounce et al., 1996).

Reactive oxygen species (ROS) assessment

Mitochondrial superoxide production was determined by fluorescent microscopy incubating cells with 2.5 μ M MitoSOX™ (Life Technologies) for 30 min at 37°C. MitoSOX-Red fluorescence was determined at 580 nm with a digital imaging system using an inverted epifluorescence microscope with 63X/1.4 oil objective (Nikon Eclipse Ti-U, Nikon, Japan). Images were captured with a back-illuminated Photometrics Cascade CCD camera system (Roper Scientific) with 500 ms exposure time and elaborated with Metamorph acquisition/analysis software (Universal Imaging Corp.).

Hydrogen peroxide was determined after incubation with 5 μ M of 2,7-dichlorodihydrofluorescein diacetate (H_2DCFDA , Life Technologies). H_2DCFDA fluorescence was measured at 535 nm using a multilabel counter Wallac 1420 (PerkinElmer, Turku, Finland).

Statistical analyses

Statistical analysis was performed using the Prism 6 software (GraphPad), choosing ordinary one-way ANOVA with multiple comparison, applying Tukey test, as correction test, or χ^2 tests

were performed, corrected with Bonferroni test. Data were considered significantly different for p-values < 0.05.
